# Preface to the Tenth Edition

THE EDITORS are pleased to present to students and physicians the Tenth Edition of this textbook. This edition reflects the many strides which have been made in Medicine during the past four years. As in earlier editions it has been attempted as far as possible to incorporate discussions of pathological physiology and disease mechanisms into the total discussion of disease. When this has not been feasible sections on metabolic and physiological processes in

health and disease have been placed in close proximity to the clinical description of the diseases to which they are particularly relevant because in terms of biological processes fragmentation of the discussion of disease is artificial. For example to achieve this end a section by Dr. Joseph W. Jailer on the physiology and metabolism of the steroids has been introduced preceding the description of diseases of the adrenal and sex glands.

The Tenth Edition contains the following articles on subjects which have not been covered in previous editions

Adenoviral Infections  
Pharyngoconjunctival Fever  
Cytomegalic Inclusion Disease  
ECHO Viral Infections  
Cranuloma Inguinale  
Erysipeloid of Rosenbach  
Diseases Due to Atypical Acid Fast Bacilli  
Tropical Ulcer  
Heterodera Radicicola  
Cranial (Temporal) Arteritis  
Thrombotic Thrombopenic Purpura  
High Altitude Sickness  
Silo Filler's Disease  
Salicylate Poisoning  
Metal Fume Fever  
Pantothenic Acid Deficiency  
Renal Glycosuria  
Oxalosis  
Aminoacidurias  
Renal Hypophosphatemia  
Renal Tubular Acidosis  
Agammaglobulinemia  
Carcinoidosis  
Hyponatremia and Hypokalemia  
Steroid Physiology and Metabolism  
Hyperaldosteronism  
Acute Pseudomembranous Enterocolitis  
Hepatic Coma  
Cystic Fibrosis of the Pancreas

Dr. Yale Kneeland  
Dr. Yale Kneeland  
Dr. Edwin D. Kilbourne  
Dr. Robert H. Huebner  
Dr. Walsh McDermott  
Dr. Karl F. Meyer  
Dr. Burns Amberson  
Dr. Thomas B. Turner  
Dr. Harold W. Brown  
Dr. A. McGehee Harvey  
Dr. A. McGehee Harvey  
Dr. Robert C. Darling  
Dr. William J. McConnell  
Dr. Henry Aranow, Jr.  
Dr. Henry Aranow, Jr.  
Dr. Tom D. Spies  
Dr. Alexander B. Gutman  
Dr. Alexander B. Gutman  
Dr. Alexander B. Gutman  
Dr. Alexander B. Gutman  
Dr. Alexander B. Gutman  
Dr. Charles A. Janeway  
Dr. Albert Sjoerdsma  
Dr. Robert Berliner  
Dr. Joseph W. Jailer  
Dr. George W. Thorn  
Dr. Walter L. Palmer  
Dr. Arthur J. Patek  
Dr. Paul H. di Sant Agnese

Cryoglobulinemia and Macroglobulinemia  
 Myeloproliferative Disorders Including  
   Myeloid Metaplasia  
 Cervical Spondylosis  
 Benign Intracranial Hypertension  
 Electric Shock Treatment in Psychiatric  
   Therapy  
 Tietze's Syndrome  
  
 Marfan's Syndrome

Dr Alfred Gellhorn

Dr William B Castle  
 Sir Russell Brain  
 Dr Bronson S Ray

Dr Peter F Regan III  
 Dr Walter Bauer  
 Dr Frederic C Barter  
 Dr Walter Bauer  
 Dr Frederic C Barter

Despite the inclusion of this new material there has been no sacrifice of clinical considerations. This has been achieved by utilizing a new and clearer type which makes possible an increase in the text without an increase in the number of pages.

It is with regret that the Editors report the deaths of the following contributors: Dr Janet S Baldwin, Dr Thomas A C Rennie and Dr Ephraim Shorr. The following new contributors have written sections formerly covered by those lost by death or retirement: Dr Robert B Aird, Dr Henry Aranow Jr, Dr Harry L Arnold, Dr Richard G Bing, Sir Russell Brain, Dr Harold W Brown, Dr C Lee Buxton, Dr Ronald V Christie, Dr Alfred Gellhorn, Dr Melvin M Grumbach, Dr Franz J Ingelfinger, Dr Joseph W Jailer, Dr Robert A Kehoe, Dr Lawrence C Kolb, Dr Herbert Koteen, Dr Charles A Le Maistre, Dr Fletcher H McDowell, Dr George A Perera, Dr Peter F Regan III, Dr Arnold S Reiman, Dr Lamar Roberts, Dr Paul A di Sant Agnese, Dr R Walter Schlesinger, Dr Albert Sjoerdsma, Dr John B Stanbury, Dr DeWitt Stetten, Dr John V Taggart, Dr David Weiman, Dr Eric Wolfaardt and Dr Sam Bernard Wortis.

It is axiomatic that however excellent the content of a textbook may be its usefulness to the student can be measured by the completeness of its index. With this point of view in mind the Editors have laid unusual emphasis upon the preparation of an index which will enhance the value of the book.

The Editors wish to direct the attention of the reader to the Foreword by Dr Dana W Atchley. The impressive data presented in the subsequent 1600 pages are of limited value in the actual practice of medicine unless they are considered within the framework of the timeless philosophy expressed in this Foreword which deals with the problems of Patient-Physician Communication.

The Editors extend their sincere thanks to the distinguished contributors who have written for this Tenth Edition. Without their full cooperation this textbook would not exist. They also wish to express their appreciation to the officers and staff of the W B Saunders Company for their constant help and advice. Grateful acknowledgment is due Mrs Ann Tourtellot for proofreading and editorial work.

# A Foreword

## PATIENT-PHYSICIAN COMMUNICATION

Osler early in this century quoted Galen as saying "He cures most successfully in whom the people have the greatest confidence." This long recognized truth is so important that it would seem appropriate to consider in a brief foreword some of the qualities of the physician as healer that are as essential to his success as is the scientific knowledge he can gain from text book or journal. A familiarity with disease patterns and an understanding of their mechanisms are of course essential to the sound practice of medicine but they can be sadly inadequate in the absence of effective communication between doctor and patient. This communication must be in both directions as much from the doctor to patient as the reverse and it should be on as many levels as is mutually possible. It is not surprising that the increasingly accurate comprehension of disease processes has tended to emphasize the essential individuality of patients in all respects. This individuality is particularly evident in the variations of personality and full comprehension of personality is gained only by good communication.

A sympathetic and discerning history provides the first and most important step as the patient and doctor come to know each other. While the unhurried interviewer listens responsively to the ill person's problems a rapport is established that can soon be turned to an investigation of family marriage work and other environmental factors from which the portrait of a single

human being emerges. With success this portrait quickly comes to life first as an acquaintance and then as a friend. Success is dependent on a convincing expression of real interest and on equally genuine evidence that the doctor cares whether his patient is sick or well, happy or unhappy. The doctor who must force himself to listen to patients or finds himself indifferent to suffering should transfer to a branch of medicine that does not involve personal relationships with the sick.

Communication on the emotional level is therefore a basic necessity for initiating relationships at other levels. Warmth and compassion break down the barriers of anxiety and fear that beset the patient coming as a stranger to the doctor, barriers that can seriously inhibit the thoroughness of a diagnostic appraisal. If a patient feels that his problems are provocative not only of scientific interest but also of a deep concern over his happiness he will be more open in discussing his life and his deeper feelings and also more cooperative in accepting unpleasant diagnostic and therapeutic procedures. A good emotional rapport between the doctor and his patient improves his efficiency as a healer and indeed makes the whole process more pleasant. The physician should be careful not to give too much of himself emotionally or he will be in danger of losing his objectivity and perhaps his poise. He must not dispel the patient's anxiety by taking it on to himself. The devotion to which

### *Patient Physician Communication*

at least minimal unhappiness and situations can arise wherein this goal might be defeated by austere frankness. Sophisticated and compassionate physicians are faced with the question whether they may claim for themselves the serious authority of deciding to protect a patient from devastating truth. Of course mature and intelligent insistence on the complete picture cannot be refused but such a request is rare more often such a demand from the patient is in reality based on an anxious and unconscious search for reassurance. It is this latter group that imposes the most difficult responsibility upon the physician he may share it with his colleagues or with the patient's relatives but the ultimate painful decision is his. The truth should be adhered to as far as is humanely possible but if the physician should deem it wise to veil the truth the presentation should be so convincing that the dire effects of discovery will never ensue. In any event the truth should be tempered with mercy because of the fallibility of prognosis. It is difficult to subject any area of human relations to dogmatic ethical codes rigidly imposed and especially is this true in relation to suffering human beings. Each case must be handled individually with one guiding principle to provide

minimal unhappiness for all concerned and an outlook compatible with living.

A most important but rarely mentioned component of doctor patient communication is *humor*. A light touch may not be life saving but it can lift many clouds of depression and anxiety. It is the best ice breaker for the patient frozen by fear or by the strangeness of medical routines. Stilted Pollyanna reassurances are of little value indeed may be harmful but a wry comment on the absurdities of some medical customs can leave a patient smiling and cooperative. This level of communication should never be neglected and its constructive value never discounted.

When all the gain from good communication has been achieved and all knowledge from textbook and technical studies has been mobilized there is a final step that is no less crucial than are all the others. This is the wise and scientific integration of all the varieties of data into the biological portrait of a single human being. This is the art of medicine and like all great art it is the skillful and creative application of a scientific discipline to a human problem.

DANA W. ATCHLEY

## Patent Physician Communication

the sick person is so vulnerable is easy for the doctor to exploit. It can be an effective agent for the enforcing of therapeutic management but it can also cause many painful complications if it is not employed wisely and unselfishly.

*Communication on a cultural level* is enriching to the patient-doctor relationship. This can be based on a mutual interest in the arts, literature, history or even politics. Or it can be an interchange between two individuals who have experienced different environments. Learning about other strata of society or different national and ethnic backgrounds is rewarding to the doctor and is of practical value when he plans his patient's management. The facts that appear at this level of contact are probably more nearly accurate than any the physician can find elsewhere. The medical profession is fortunate in being able thus to tap original sources of information; it is one of its greatest rewards. And the patient also profits as he is exposed to the disinterested comments of a wise and cultivated scientist. Here again the doctor and patient give of themselves in happy interchange.

Although confidence may be initiated on the emotional level, a firm foundation requires *communication on an intellectual level*. The first step at this level is a careful explanation of the nature and purpose of the physical appraisal. It is obviously necessary for the doctor to be scientifically trained and for the patient to have a certain degree of intelligence and education. Both of these conditions are increasingly fulfilled in our present society. Only the uninformed are benefited by the secretive authoritarianism used in previous centuries to mask ignorance. Although some men have a greater gift of exposition than others and patients vary in their receptivity, it is a rare situation in which the disease mechanisms and their clinical setting cannot be so adequately explained to the patient that his management can proceed from understanding rather than blind faith. More and more the psychic and somatic individuality of human beings requires that the experimental method be the basis of their treatment. Patients therefore must learn the elements of this method and carry out much of the experimentation under their own supervision. Without good expository communication such programs will

inevitably fail. Unfortunately many such failures derive from the doctor's own lack of understanding or worse his lack of interest.

The level of *mutual integrity in communication* is so vital to good doctor-patient relationships that it may almost be given top priority. There is no excuse for the physician who fails here, but deception on the part of the patient is often the manifestation of a neurosis. Such dishonesty is clinical, not ethical. The basic integrity of the physician in relation to a patient deserves attentive consideration and has many complex implications. The doctor must be honest within himself; he must face his motivations clearly and candidly. He must not over-restrict his patient to protect himself. His prognoses must not be hedged out of fear for his own reputation for accuracy. He must have the honesty and courage to admit his mistakes to patients when indicated, but always to himself and his colleagues.

It is essential that the patient trust his doctor; he must know that his confidences are never broken. However the impingement of simple ethics on the physician's sense of responsibility to his patient creates a number of subtle conflicts between duty to code and duty to patient. Much has been said with considerable heat on the question "Shall the patient be told the strict truth?" This problem has two phases: on one hand the revealing of facts that are clearly not disturbing to the patient that are indeed essential to intelligent cooperation, and on the other hand the *impairing* of information of such dread import that hope and happiness are forthwith destroyed.

The first phase needs little discussion. It should be accomplished with calm exposition rather than dramatic declarations. If the studies have revealed no clear answer the doctor's "I don't know" should never seem to indicate cessation of interest. It should have continuity inherent in its mood.

The transmission of bad news may require only optimistic slanting without actual falsity; there need be no trauma here to the physician's values. The real problem lies in the area where evasion might be deemed advisable. The ultimate goal of medicine is conceded to be happiness or

# The Infectious Diseases

## VIRAL DISEASES

### Introduction

Infectious diseases are usually classified according to the kind of infectious agent which induces them. The clinical manifestations of these various diseases differ widely and the agents which cause them are also dissimilar. The following groups of infectious agents are recognized: protozoa, fungi, bacteria, rickettsiae and viruses. These causal agents have a single property in common: all are capable of multiplication in an appropriate environment. The degree of their structural differentiation as well as their size decreases from the protozoa to the viruses in the order given. Viruses are the smallest of known agents capable of inducing infectious disease. One or another of the pathogenic agents included among the viruses is either known or believed to be the primary cause of each of some fifty different infectious diseases of man. These are:

Adenovirus infections  
B virus infection  
Cat scratch fever  
Colorado tick fever  
Common cold  
Coxsackie and ECHO virus infections  
Dengue  
Durand's disease  
Encephalitis lethargica  
Encephalitis Japanese type B  
Encephalitis Murray Valley type  
Encephalitis Russian Far East type  
Encephalitis St. Louis type  
Encephalitis West Nile type  
Encephalomyocarditis  
Epidemic pleurodynia  
Epidemic viral gastroenteritis  
Equine encephalomyelitis Eastern  
Equine encephalomyelitis Venezuelan

Equine encephalomyelitis Western  
Equine infectious anemia  
Exanthem subitum  
Foot and mouth disease  
Hemorrhagic meningo-encephalitis  
Herpes simplex  
Herpes zoster  
Inclusion conjunctivitis  
Infectious hepatitis and serum hepatitis  
Infectious mononucleosis  
Infectious polyneuritis  
Influenza (A, B and C)  
Kerato-conjunctivitis  
Louping ill  
Lymphocytic choriomeningitis  
Lymphogranuloma venereum  
Measles  
Molluscum contagiosum  
Mumps  
Newcastle disease  
Phlebotomus fever  
Pollomyelitis  
Primary atypical pneumonia  
Psittacosis  
Rabies  
Rift Valley fever  
Rubella  
Salivary gland virus infection  
Smallpox  
Trachoma  
Vaccinia  
Varicella  
Warts  
Yellow fever

The nature of viruses is not yet definitely known, but certain facts appear well established. Viruses are particulate entities which can be visualized by sufficiently powerful instruments, e.g. the electron microscope. Multiplication of viruses occurs under suitable conditions in the presence of living cells, but in the absence of living cells no virus has as yet shown any evidence of multiplication. Discontinuous variation has been observed with certain ones

widespread of all infections and is a leading cause of minor incapacitation and absence from work. It is not an entity but rather a diagnostic residuum after the exclusion of disease caused by such recognizable agents as the influenza viruses or streptococci.

Extensive studies in the U S Army during World War II by the Commission on Acute Respiratory Disease resulted in the separation on clinical grounds of two conditions designated "Acute Undifferentiated Respiratory Disease (ARD)" and "Nonstreptococcal Exudative Pharyngitis." These two together with certain other clinical conditions have recently been shown to be caused by infection with a newly identified group of viruses called "adenoviruses." The whole subject of common respiratory disease will be presented under two headings: The Common Cold and Adenoviral Infections.

### THE COMMON COLD

(Acute Coryza)

**Definition** The common cold is an acute inflammation of the upper respiratory tract which is ordinarily communicable and caused by a filterable virus. Such terms as "acute rhinitis," pharyngitis and laryngitis have often been used to denote the area chiefly involved.

**Etiology** Kruse in 1914 was the first to adduce evidence of a filterable virus in colds. These observations were considerably extended by Dochez and his co-workers who repeatedly demonstrated the presence of a filterable agent in acute coryza capable of causing colds when introduced into an antheroid ape or a susceptible human volunteer and succeeded in cultivating it in tissue culture medium and the developing chick embryo. These filterable agents were obtained early in the course of the coryzal type of cold and the experimental disease had a short incubation period of twelve to forty-eight hours. The cultivation of the cold virus has been confirmed by certain writers but others have failed to do so; it would appear from the inconstancy of the results that the agent is not readily adapted to the chick embryo. The work on filtrate colds however has been abundantly repeated. Moreover there is very recent preliminary evidence that new techniques of virus cultivation may yield positive results. There seems little doubt therefore that a filterable virus of the common cold exists and presumably is the causative agent in the great majority of cases, notably of the epidemic type. A great deal however still remains to be elucidated. It is

not known how many different cold viruses there are; there is no precise information as to how long the virus is carried in the respiratory tract or what the conditions of transmission may be; and little knowledge concerning immunity to colds is available. Moreover it cannot be said with certainty that under certain conditions the common respiratory pathogenic bacteria do not initiate colds although the evidence is against this possibility. Studies of small isolated communities such as those conducted by Paul and Freese in Spitzbergen imply that in the absence of the virus the common cold almost wholly disappears. Presumably the residuum of sporadic noncommunicable colds may be due to bacterial infection.

In spite of extensive investigation for many decades the exact role of the bacterial inhabitants of the nasopharynx is not clear. Most students agree that a considerable part of the so-called basal flora of the upper respiratory tract consists of nonpathogenic and inconsequential agents. In this category would be placed the various *Neisseriae*, diphtheroids, nonhemolytic streptococci, most of the staphylococci and so on. On the other hand hemolytic streptococci, pneumococci and *Hemophilus influenzae* are proved respiratory pathogens and when they are recovered in considerable numbers from a patient with a cold it is tempting to assume that they are playing a role of some sort. Undoubtedly hemolytic streptococci can initiate exudative pharyngitis without any assistance from a filterable virus as evidenced by the food and milk borne outbreaks of this disease. Perhaps *H. influenzae* can in unusual circumstances do the same sort of thing as in "Woodside throat" which was described in the Australian Army at the outbreak of World War II. On the other hand any of these organisms may appear in the normal nasopharynx without causing symptoms and the mere recovery of one of them from a case of coryza may be of little significance. Most authors tend to designate them as secondary invaders, assuming that the cold virus paves the way for their entry into the mucous membranes. Yet when effective chemotherapeutic agents have been used in large scale controlled experiments on adults with colds there is little evidence that suppression of the bacterial component alters the average duration of the disease. Perhaps the best way to define the activity of the bacteria is in relation to the susceptibility of the population under scrutiny. Infants and small children to

Viruses differ widely in size stability and degree of apparent structural differentiation

The smallest viruses (with dimensions of 10 to 28  $m\mu$ )—*e.g.* those responsible for foot and mouth disease and poliomyelitis—are particles only slightly larger than serum globulin molecules and are actually considerably smaller than the hemocyanin molecules of certain animal species. The largest viruses (with dimensions of 225 to 400  $m\mu$ )—*e.g.* those of psittacosis and vaccinia—are but little smaller than certain bacteria and are in fact larger than pleuropneumonia organisms. Between these two extremes the viruses form an almost unbroken series in regard to their size at one end the dimensions of viruses overlap those of protein molecules and at the other those of living microorganisms. Vigorous discussion has centered around the question: Are viruses living or nonliving entities? Viruses have certain properties which are usually attributed to living things as well as certain others which are usually associated with nonliving things and there is as yet no satisfactory basis upon which to determine the relative viability or nonviability of these infectious agents. At the present time it is convenient to think of viruses as obligate intracellular parasites of very small size.

The pathological changes resulting from infections by viruses depend primarily upon alterations in cell metabolism which are induced by the presence of a virus. The nature of these aberrations is not fully understood. It is known that different viruses affect the same cells in different ways and it is well established that certain viruses selectively infect different types of cells. Consequently it would be expected that viral diseases might present exceedingly diverse clinical manifestations and that the ultimate pathological changes would be dissimilar. This is in fact the case as will be evident from a consideration of the foregoing list of widely different infectious diseases each of which is either known or believed to be induced by a particular virus. The primary pathological phenomena common to all viral diseases appear to be the following: hyperplasia, hyperplasia accompanied by necrosis and necrosis. Some viral diseases are characterized by the occurrence of inclusion bodies in affected cells; others do not show these peculiar morphological elements. The exudative phenomena commonly associated with inflammation occur in varying degrees in most viral diseases but are thought to be secondary to the changes induced by the virus in cells of the infected tissues.

An enduring immunity develops after many but not all viral diseases; those not followed by persistent immunity are common cold, influenza and herpes simplex. This phenomenon serves additionally to distinguish viral infections from diseases caused by most other infectious agents. The basis for the lasting immunity which follows most viral diseases is not known. It is thought that changes induced as a result of the intimate association between virus and infected cell or the prolonged possibly persistent presence of some viruses in infected hosts may account for the continuing immunity. It is because of the prolonged active immunity of many viral diseases that specific prophylactic measures have been so effective in protecting against some of them—*e.g.* smallpox and yellow fever.

At the present time almost no effective specific therapeutic measures have been devised for viral diseases. However, some diseases caused by the largest of known viruses—*e.g.* the psittacosis lymphogranuloma venereum group—appear to be favorably influenced by various chemotherapeutic substances. Therapy with specific antiserum apparently is of no value once clinical manifestations of the infection have ensued since by this time the virus is widely disseminated in the infected tissues and most susceptible cells have already been affected. During the incubation period that is before wide dissemination of the virus has occurred, specific immune serum appears to be useful as a preventive measure in a few viral diseases—*e.g.* measles.

## Common Upper Respiratory Disease

### (The Common Cold, Adenoviral Infections)

The term "common upper respiratory disease" is used to denote a group of infections of the upper respiratory tract, presumably of viral origin, which are world wide in distribution and to which the human race is almost universally susceptible. Common respiratory disease is by all odds the most

fairly abrupt and the first symptom is likely to be a sensation of soreness and dryness localized to a small area of the pharynx. Within a few hours a sense of congestion develops in the nasal passages usually accompanied by sneezing and shortly thereafter by nasal discharge which in the early stages is thin and watery. At the end of forty-eight hours the full blown clinical picture has ordinarily developed: the eyes are suffused, the voice is husky, there is fairly intense congestion of the upper respiratory mucosa with obstructed breathing, nasal discharge is abundant, the sense of smell and taste are diminished, and there is some cough. Unless the patient has a tendency to chronic bronchitis, the cough is usually nonproductive in the early stages; later on there may be some mucoid sputum. Along with these local symptoms there is a variable amount of general malaise. The patient feels lethargic and may complain of some vague aching pains in the back and limbs. Marked malaise and prostration are not features of the common cold in adults, however, and the ordinary case is afebrile throughout.

In children the disease is likely to be more severe and temperatures of 102° F or even higher are frequently noted. Malaise is more pronounced and anorexia is common. Other digestive symptoms are rare.

Once the full symptoms have developed the common cold runs a variable course. The whole illness may subside rapidly. More commonly, however, there is a period of several days of excessive nasal secretion and cough with thick mucopurulent discharge which then gradually begins to abate. Ordinarily the uncomplicated cold lasts from seven to fourteen days.

Precisely where the common cold ends and complications begin is a matter of definition. Some degree of laryngitis and tracheitis may be part of the primary picture, but clinical signs of tracheobronchitis are properly to be considered as complications in all likelihood due to secondary bacterial infection. Similarly it seems probable that there is some inflammation of the paranasal sinuses as part of the uncomplicated cold yet acute clinical sinusitis (which may occur late in the course of a cold) is a complication. Otitis media is mainly a problem for the pediatrician. It occurs most often in infancy and early childhood and may appear at any stage of the disease, although most often it is fairly early. It is more common in the winter months and is caused by the common respiratory bacterial pathogens.

**Diagnosis.** The characteristic appearance of a person with a full blown cold in the head is too familiar to require further comment. Some mention, however, should be made of the appearance of the throat. Close inspection will usually reveal a slightly shiny and edematous appearance of the mucous membrane with swelling and redness of the lymphatic aggregations. Post nasal drip may be present but is not diagnostic. True exudate on the tonsils or pharynx is not part of the picture of the common cold. Such an exudate together with swelling and tenderness of the upper deep cervical lymph nodes indicates the presence of so-called "exudative pharyngitis" caused by infection with hemolytic streptococci or by an adenovirus. On the whole, however, the adult pharynx particularly in heavy smokers may show little or no recognizable deviation from the normal in the course of an acute cold. In children on the other hand the normal pharynx is usually paler and evidences of acute inflammation are thus much easier to detect.

It must be borne in mind that there is a stage at the onset of certain specific diseases such as measles, rubella, chicken pox, pertussis, and cerebrospinal fever which may be indistinguishable from the common cold. Moreover, it is now known that infection with the viruses of influenza and atypical pneumonia may take the form of a mild disease simulating acute coryza. These entities (in the absence of pneumonia) can only be differentiated from the common cold by serological means. A purely allergic rhinitis may mimic the common cold. In this situation the history is most important in differential diagnosis and the rapid development of symptoms, the lacrimation, sneezing, itching, and the pale boggy appearance of the turbinates are fairly characteristic. An element of allergy may be present in infectious colds. This is particularly true in some of the so-called "cold susceptible" children with a tendency to asthma. In such instances the allergy is presumably directed toward bacterial products.

There are no abnormal laboratory findings in the common cold. If a leukocytosis is present it strongly suggests a bacterial complication.

Finally, it may be remarked that except in infancy the diagnosis of common cold is usually made by the patient, not the physician. His function is to exclude other conditions, to search for complications, and to institute appropriate therapy.

**Prophylaxis.** The prevention of any com-

gether with certain remote rural populations (note Burkey<sup>1</sup> and Smillie's experience in Labrador and Alabama) appear to be much more susceptible to the activity of these bacteria than do adults in urban localities. In all likelihood secondary infection with pathogenic bacteria in the young age and rural groups does intensify the local inflammation of the mucous membranes and heighten the constitutional reaction as well as prolongs the course. Support for this view is derived from the fact that antimicrobial drugs do seem to modify the severity of colds in children in contrast to the adult experience cited before. Thus it appears that most colds in adults unless they are accompanied by a purulent complication such as sinusitis or otitis are probably not much affected by the mere presence of a bacterial pathogen.

In summary it can be stated that the common cold is due to one or more filterable viruses and that only in highly susceptible persons is there an etiological complex, i.e. a bacterium acting in concert with a virus. The bacterial effect may be either the general intensification of symptoms already referred to or a clear cut complication such as purulent sinusitis or otitis.

It is to be noted that in the foregoing no reference has been made to chilling and exposure as factors in the etiology of colds. This may be surprising since the very name of the malady presupposes an important etiological relationship. Moreover it is mainly a disease of the colder months of the year and chilling of the body surface has been shown to cause vasoconstriction in the mucous membranes of the upper respiratory tract. The latter observation lends some physiological basis to the notion that chilling may reduce local resistance to infection and thus supports the age-old human belief that one can catch cold as a result of exposure. It would be rash indeed to deny that chilling has any effect on the likelihood of catching cold. It can be stated however that chilling in the absence of a primary infecting agent will not cause colds and that its role is at best a minor auxiliary one in an environment where primary agents are ubiquitous.

**Pathological Anatomy and Physiology.** In the presence of a cold there is an inflammation of the mucous membranes of the upper respiratory tract which often begins as a local affair in the throat. The most intense reaction takes place in the nasal passages, turbinates and so forth where a good deal of secretion mucoid at first and then muco-

purulent is produced. The principal pathological changes are edema, hyperemia and hypersecretion with comparatively little cellular infiltration. An appreciable amount of epithelial desquamation takes place as the disease progresses. Stained smears of the secretions show considerable numbers of epithelial cells and leukocytes and the findings of eosinophils suggests that an allergic rhinitis is present.

The effects of this disturbance are local and general. With regard to the former in addition to the difficulty in breathing and the troublesome secretions there may be symptoms from blockage of the eustachian tubes or the paranasal sinuses. The general effects presumably due to "absorption" are relatively minor particularly in adults.

**Epidemiology.** The epidemiology of colds can best be understood by remembering that they are highly communicable notably indoors and in childhood that the period of active immunity is short and that for reasons not entirely clear they appear mainly in the colder months of the year.

Many surveys of the incidence of cold have yielded various estimates of their frequency depending on the age of the group under scrutiny, its geographical location, habitat and *modus vivendi*. It seems likely that in urban communities in the temperate zone the general population averages about three colds a year. This average number is often greatly exceeded in susceptible persons, particularly children.

When the weekly incidence of common respiratory diseases is charted for large masses of population there is ordinarily a low rate during the summer, a rise in the autumn, a single high midwinter peak and a spring decline. When smaller urban groups are studied however a different pattern may appear in which not one but three peaks are discernible. The first is in early autumn and all evidence would indicate that this is a result of the reopening of schools with the massing together of young susceptibles indoors. The winter peak is often associated with an increased incidence of more severe respiratory infections such as pneumonia and may be accompanied by a wider dissemination of pathogenic bacteria. Finally there may be a smaller secondary peak in the spring.

As has been stated most colds appear to be communicable and transmitted directly by droplet infection. Susceptibility being almost universal there is no practicable method of limiting the spread of colds under the ordinary conditions of urban life.

**Symptoms.** The onset of a cold is usually

Local therapy directed toward lessening secretions and improving the nasal airway is not recommended in the early acute stages of a cold. Later on however when secretions have thickened it is often helpful not only in relieving symptoms but also in promoting sinus drainage. One per cent ephedrine in saline used either in an atomizer or in the form of nose drops is safe and relatively nonirritating. A propylhexedrine inhaler is convenient for the ambulatory patient.

A few years ago the antihistaminic drugs were introduced as therapy for the common cold and it was claimed that if they were employed early enough the disease could be aborted in a large percentage of cases. This received widespread publicity and in consequence of a tremendous advertising campaign these agents either by themselves or incorporated with other drugs have been taken by the public on a huge scale. Subsequent carefully controlled studies have quite failed to substantiate the original claims. The conclusions of the present writer based on an admittedly small series were that in perhaps one half of the cases the antihistaminics appeared to exert some benefit on the intensity of the catarrhal symptoms but that usually the fundamental course of the disease remained unchanged. Fortunately these drugs in the dosages employed have been singularly innocuous as far as untoward side effects are concerned. Nevertheless they are not recommended unless there is an allergic element present.

The routine use of antimicrobial drugs in colds is contraindicated. These drugs should be used only with a specific objective in mind: i.e. the control of bacterial secondary infection. In other words their use should be limited to those cases in which there is a strong likelihood that a complication is developing. Thus clinical signs of bronchopulmonary infection, sinusitis or otitis media are indications for their use. The use of antimicrobial drugs may also be justified in highly susceptible persons who give a history of the regular occurrence of complications with their colds. In such cases penicillin is the safest and most generally desirable agent. A daily intramuscular injection of 1 ml. of a mixture containing 300 000 units of procaine penicillin and 100 000 units of crystalline penicillin is recommended. The suggestion of parenteral rather than oral penicillin is deliberate for the latter is so much easier to administer that it leads to much more indiscriminate use. It must be borne in mind that as time

goes on more and more persons disclose some sensitivity to penicillin and the drug should not be used without reasonable indications. Obviously if it is employed the patient's past history in regard to penicillin therapy must be queried. The tetracyclines and chloramphenicol are not recommended for routine use owing to their side effects.

The treatment of subacute and chronic complications of the common cold is outside the scope of this discussion. In adults the treatment of these complications usually falls into the purview of the otolaryngologist. The pediatrician too is confronted with a small group of children often of the "allergic" type who may be literally incapacitated by recurrent upper respiratory infections. For such cases many expedients have been tried: sulfadiazine or penicillin prophylaxis, injections of stock and autogenous bacterial vaccines, bacterial filtrates and similar procedures. Change of climate is sometimes an essential recourse in the treatment of these recurrent respiratory infections. Lastly it may be mentioned that in elderly people with chronic pulmonary emphysema and a tendency to bronchitis antimicrobial therapy is often indicated from the onset of an acute cold.

#### ADENOVIRAL INFECTIONS

In 1953 Rowe and others reported the discovery of masked viral agents from surgically removed human adenoids which produced cytopathogenic effects in tissue culture. Almost immediately thereafter Hilleman and co-workers described similar viral agents recovered from military personnel with acute respiratory disease (ARD) and produced serological evidence that they were the cause of the infection. One of Hilleman's strains designated at the time "RI 67" was subsequently studied by Dingle. He had luckily preserved acute and convalescent sera from cases of ARD observed during World War II and the rise in antibody clearly demonstrated that RI 67 had been the cause of this disease a decade earlier. These discoveries were obviously of major importance and have led to an enormous amount of research. It was soon recognized that Rowes and Hilleman's agents belonged to the same general group for which the title "adenovirus" has now been adopted. New information is constantly being made available about adenoviruses but there are now enough basic data so that it is safe to outline certain generalizations concerning them.

Adenoviruses multiply readily in tissue cultures composed of various cell lines both

municable disease may be attempted by interrupting the lines of communication or increasing the resistance of the person. In a disease such as typhoid fever both methods are used with success. It is obvious that the common cold falls into a different category. As the malady is ubiquitous and noninfectious, strict isolation is not a practicable measure. Under conditions of urban life exposure is inevitable. This must not be construed as an argument for total defeatism. When one is dealing with highly susceptible groups such as nursery schools every endeavor should be made to exclude children in the acute stages of a cold. Attempts to effect quarantine in the home and the wearing of masks may be laudable but are usually doomed to failure. Recently the use of germicidal aerosols and ultraviolet light barriers have been extensively studied. It is obvious that these measures have a limited application but it has been shown that ultraviolet light if properly applied seems to prevent cross-infection in nurseries. It is costly however and warranted only when special small populations are at risk.

Attempts to increase individual resistance to an infection may be either specific or general. In regard to the first it may be stated that there is no specific vaccine against the common cold and vaccination with virus containing material has up to the present been unsuccessful. Indeed in a disease which leaves so short a period of active immunity in its wake this is not surprising. Moreover in experimental transmission of the common cold it has been shown that there is little resistance to homologous reinoculation after a brief period of time. In a somewhat different category are the so-called cold vaccines composed of mixed bacterial antigens which are supposed to enhance resistance to the secondary invaders. On the whole these have been disappointing and most large controlled studies indicate that they are not effective in reducing the incidence of or invalidism from colds. In the occasional patient who is highly susceptible to bacterial complications the vaccines have at times appeared to be of some limited benefit.

The general measures are mainly concerned with nutrition, hygiene, hardening procedures and the eradication of focal diseased areas. Here again the record is a disappointing one. There is no statistical evidence in controlled studies that the state of nutrition, the addition of vitamins in excess, the type of clothing worn, exposure

to sunlight, fresh air and similar measures have any effect on susceptibility to colds. In regard to the presence of diseased tonsillar and adenoidal tissue there is some difference of opinion. Though the removal of tonsils is generally admitted to influence recurrent severe streptococcal throat infections, its effect on colds is debatable. In all likelihood the presence of adenoid tissue influences the severity of colds in early childhood. On the other hand surveys of older children indicate that there is little difference in cold susceptibility between those who have undergone tonsillectomy and adenoidectomy and those who have not.

Long term chemoprophylaxis with small doses of sulfadiazine or oral penicillin will strikingly reduce the incidence of streptococcal infections. There is also evidence that it may reduce the severity of common respiratory disease in highly susceptible infants or children. In adults on the other hand such chemoprophylaxis appears to have relatively little effect.

**Treatment.** Up to the present no specific agent has been developed which is effective against the virus of the common cold. In consequence therapy is directed at general management, relief of symptoms and the control of complications.

In ideal circumstances it would probably be advisable to treat all sufferers from the common cold with rest and isolation but in practice this is impossible. Bed rest should however be enforced in the more highly susceptible, i.e. infants and young children and in adults with temperatures over 100° F or some complicating chronic disease.

Symptomatic relief in the very young can usually be afforded by small doses of acetyl salicylic acid (aspirin). In adults particularly if cough is troublesome it is customary to give some codeine as well. This may be administered in the form of codeine cough mixture or in the traditional gripe capsule. The following prescription has the weight of tradition behind it and is effective.

Codeine sulfate	0.015 gm
Acetylsalicylic acid	0.3 gm
Phenacetin	0.12 gm
Caffeine citrate	0.03 gm

One of these capsules may be given every three or four hours.

Capsules containing 0.015 gm each of codeine and papaverine are also popular and it has been suggested that they may aid in "aborting a cold." In the writer's experience they do not do so but are merely symptomatic in their effect.

Local therapy directed toward lessening secretions and improving the nasal airway is not recommended in the early acute stages of a cold. Later on however when secretions have thickened it is often helpful not only in relieving symptoms but also in promoting sinus drainage. One per cent ephedrine in saline used either in an atomizer or in the form of nose drops is safe and relatively nonirritating. A propylhexedrine inhaler is convenient for the ambulatory patient.

## Influenza

### (Grip Catarrhal Fever Epidemic Influenza)

**Definition** Influenza is a specific infectious disease of man caused by a virus of the influenza group. The disease is an acute self limited infection and is characterized by constitutional symptoms although the infection is restricted to the respiratory tract. It occurs most commonly in epidemics of varied size. Between epidemics sporadic cases are encountered. Three distinct etiological types of the disease are known: influenza A, influenza B, and influenza C. Influenza A occurs more commonly than influenza B, influenza C appears to be rare. A distinction between the etiological types cannot be made on clinical or pathological grounds. The disease is usually of short duration and is rarely serious. Complications are uncommon but may be severe, particularly if secondary bacterial pneumonia develops. The cause of the great pandemic of 1918-1919 has not been decisively established.

**History** The disease has been recognized since ancient times. Many widespread epidemics and oc-

casional great pandemics have occurred during the past four centuries. In recent times extensive pandemics appeared in 1889-1892 and 1918-1919. The latter affected persons in all areas of the earth and is thought to have led to the death of about 20,000,000 people. Much the most common cause of death was secondary bacterial pneumonia.

Modern knowledge of influenza stems from the discovery by Smith, Andrews and Laidlaw in 1933 that the disease is caused by a virus. This agent is now designated influenza A virus. Epidemics of varying extent have occurred frequently during the past twenty years, recently they have appeared almost yearly, but the disease involved has not been commonly associated with complications. In 1940 Francis and Magill independently discovered influenza B virus. This agent is unrelated antigenically to influenza A virus, one does not produce immunity against the other. That the two major types of influenza now designated A and B are caused by influenza A virus and influenza B virus respectively is generally accepted. In 1949 Taylor discovered influenza C virus. This agent is unrelated antigenically to either influenza A or B virus. Relatively few patients with influenza C have been studied and far less is known of this disease than of influenza A or B. In the absence of satisfactory material from patients with the pandemic disease of 1918-1919 it has not been possible to determine whether any of the known influenza viruses or some other infectious agent was the primary causal factor.

**Etiology** The disease is caused by a virus of the influenza group. This agent is spherically shaped and of medium size, about 100 m $\mu$  in diameter. During the acute phase of the disease the virus is present in the respiratory tract but not in other areas of the body nor in the blood. Sputum, saliva and nasal secretions contain the agent. It can be demonstrated in washings of the nose or throat from the first day of illness to the fifth. There are three distinct and immunologically unrelated serological types: influenza A, influenza B, and influenza C virus. Influenza A and B viruses are infective for ferrets, mice, hamsters and chick embryos. Influenza C virus appears to be infective but less virulent for most of these species, although it has not caused infection in mice. Animals appear not to be infected by these agents in nature and there is no evidence for an interepidemic reservoir for the viruses other than man himself. Usually the agents are recovered from throat washings of patients by inoculation into the amniotic sac of chick embryos. With the exception of swine influenza virus, which is immunologically related to some strains of influenza A virus, no other virus is known to be serologically related to any of the agents in the influenza group. Progressive variation in antigenic composition, particularly marked with influenza A and B viruses, is more striking than with any other virus infecting man, and has seriously affected efforts to prevent the disease with

vaccines Influenza viruses like vintage wines vary unpredictably from year to year Influenza A virus has shown particularly striking alterations In 1946-1947 the antigenic composition changed so much that vaccines made from earlier strains became ineffective the new strains were designated "A prime" In 1957 even more marked alterations in antigenic composition occurred which again made earlier vaccines obsolete and resulted in the much publicized designation "Asian" influenza

Infection or immunization with influenza A virus does not lead to immunity against influenza B or C virus and vice versa Despite these striking immunological differences the agents possess many common properties One of the most useful is their capacity to cause agglutination of erythrocytes *in vitro* a reaction which has provided simple techniques for identification and measurement of the viruses or antibodies against them An increase in antibodies against the type of virus which caused the infection may be demonstrated seven to ten days after the onset of illness the maximal antibody response is observed two to four weeks after onset Antibody levels against a soluble antigen of the virus are measured by complement fixation against the virus itself by hemagglutination inhibition or by neutralization *in vivo* Because many persons of school age or older possess antibodies against each of the three types of virus in their serum measurement of the antibody levels in a single serum specimen is not helpful in reaching an etiological diagnosis A comparison of the antibody levels in acute phase and convalescent serum specimens is the most reliable means of establishing the diagnosis and the etiological type of the disease

**Incidence and Epidemiology** Although occasional sporadic cases occur during inter epidemic periods they do not often lead to many secondary cases among contacts In influenza appears most commonly in epidemics which may be localized or widely spread During the past twenty years epidemics have broken out in some parts of the world almost annually Localized epidemics may appear nearly at the same time in different areas even in different countries or large epidemics may seem to spread from one area or country to another Pandemic outbreaks have appeared only rarely and have been separated by long intervals of varying duration The pandemics of 1889-1892 and 1918-1919 which were of undetermined etiology were separated by

about twenty nine years those of 1918-1919 and 1957 *ie* "Asian" influenza by about thirty nine years

Although epidemics tend to appear during winter months they may occur at any time of the year even in the summer Large epidemics show some cyclic tendency those of influenza A have occurred at about two to three year intervals while those of influenza B have appeared roughly at four to five year intervals Epidemics of influenza A tend to be more extensive than those of influenza B Occasionally the two diseases occur in the same epidemic and rarely concurrent infection with the two viruses may develop in the same patient The attack rate may vary widely in different epidemics from as low as 1 to 2 per cent to as high as 20 to 30 per cent Usually the more crowded the conditions of living the higher is the attack rate Under conditions of crowding epidemics build up rapidly and then quickly "burn out" the whole occupying no more than two to three weeks In dispersed populations events are less dramatic and the epidemic may smolder along for two to three months

Persons of any age or race and of either sex are about equally susceptible Transmission is probably through infective droplets distributed from the upper respiratory tract which is also the portal of entry for the virus The existence of persistent carriers of influenza virus has not been demonstrated It is thought that the viruses are maintained during interepidemic periods by a chain of sporadic infections in man Infection with the agents is very common and after five years of age most persons possess specific antibodies in their serum Inapparent or subclinical infections are at least as frequent as is the manifest disease and account in part for the high incidence of antibodies against the viruses in the serum of healthy persons Neither influenza A nor B leads to persistent immunity second infections of the same type may develop after six to eight months Influenza A induces no immunity to influenza B and vice versa Resistance to infection is directly correlated with the type specific antibody level in the serum the higher the titer the less likely is infection

**Morbid Anatomy** Little is known of the pathological alterations associated with uncomplicated influenza in man In the ferret the virus causes necrosis of the respiratory epithelium of the nasal mucous membrane In man fatal attacks are commonly complicated by secondary bacterial infection

Many of the pathological changes seen may be largely attributable to the latter. In such cases there is tracheal and bronchial inflammation with marked epithelial desquamation and some epithelial necrosis. Extensive bronchopneumonia or interstitial pneumonia is usually present. During the 1957 outbreak some fatal cases occurred without evidence of bacterial infection. In most instances there were antecedent cardiac valvular lesions and extensive hemorrhage and inflammation was found in the lungs.

**Pathological Physiology and Chemistry**  
The leukocyte count is commonly within the normal range. Leukopenia when it occurs is found early in the disease usually in patients with high fever and marked symptoms. The differential leukocyte pattern is usually normal even if leukopenia is present. The erythrocyte sedimentation rate is increased. The urine is usually normal although slight albuminuria may occur. In the uncomplicated disease cyanosis is not present, cultures of the blood are sterile and the roentgenogram does not show evidence of pneumonia in the great majority of patients. The evidences of toxicity and the marked prostration so commonly seen may be attributable to toxic properties of the virus itself.

**Symptoms** Both influenza A and B lead to an array of clinical pictures which vary widely in severity and duration. Neither of the infections produces signs or symptoms which are pathognomonic. Too little is known as yet about influenza C to permit generalization.

The incubation period of influenza A or B is usually only one or two days and the onset generally is abrupt. The first and most prominent symptoms are constitutional. In the more typical cases these are commonly chilliness or a frank chill, fever, headache, malaise, lassitude, anorexia and muscular pains. Prostration of varying degree is common. Symptoms referable to the respiratory tract usually are not marked and consist of sneezing, nasal irritation or discharge, fullness or irritation of the nasopharynx, larynx or trachea. Cough is common but usually is not productive. Epistaxis, hoarseness, nausea or substernal pain may develop. In the less typical cases similar symptoms usually appear but may vary markedly in degree. In some patients the disease may simulate any of the minor acute respiratory infections. In other patients the disease may resemble more severe or generalized infections.

Fever is commonly remittent and usually persists for two or three days; the range is

one to six days. Generally the highest temperature is between 101° and 103° F, though in the more severe cases it may reach 105° F. Commonly the fever is highest on the first or second day of disease. The pulse rate is increased generally in proportion to the fever and may be quite rapid. The respiratory rate is normal or only slightly increased.

Physical signs usually are neither definite nor striking. The face may be flushed and the conjunctivae are sometimes injected. The nasal mucosa may be somewhat injected and swollen. The fauces, soft palate and posterior pharynx may be mildly injected and the lymphoid follicles may be prominent. The physical signs over the chest are usually normal although fine moist rales may be found in the lower lung fields posteriorly. Definite signs of pulmonary consolidation occur only in rare instances and commonly are indicative of secondary bacterial infection. The remainder of the physical examination does not ordinarily reveal abnormal findings attributable to influenza.

**Course and Complications** The severity of the infection and the course of the illness vary widely. Usually patients are not acutely ill for more than three to five days though some may be miserable for a week or more. The fever tends to come down by lysis and thereafter symptoms gradually disappear. Convalescence is commonly uneventful and may be fairly rapid in previously healthy persons. Patients with marked symptoms may complain of considerable prostration, increased sweating and fatigability for a week or more after fever has disappeared.

The infections which occurred during the pandemic disease of 1918-1919 were in general more severe than those which have developed during the two decades since influenza viruses were discovered. In this pandemic pneumonia appeared in many patients and was the major cause of death. Usually the first evidence of pneumonia developed two to four days after the onset. In some patients very severe or fulminating infections occurred and rapidly were fatal. In others pneumonia did not develop until the acute phase of the initial infection was over. The pneumonia was attributable to bacterial infection in almost every instance and a variety of bacterial species was associated with the infection. Staphylococci, beta hemolytic streptococci, *H. influenzae* and pneumococci were the most frequent invaders. Infection of the pleura and empyema were common complications usually

associated with beta hemolytic streptococci or pneumococci. Occasionally lung abscess developed following staphylococcal or beta hemolytic streptococcal infection. Bronchiectasis, chronic bronchitis or pulmonary fibrosis sometimes developed.

In striking contrast is the experience of the past two decades with epidemics of influenza of known cause. During this period previously healthy persons who contracted either influenza A or B only rarely developed serious complications. A small number of attacks of influenza have been associated with staphylococcal pneumonia and some with pneumococcal pneumonia but in the great majority of patients frank pulmonary disease has not occurred.

The experience gained during the extensive outbreak of 1957 has raised the possibility that in patients with marked cardiac disease pulmonary infection with the virus can be serious and perhaps fatal.

**Diagnosis** During an epidemic of influenza the diagnosis is usually not difficult because of the fairly typical clinical picture presented by the majority of patients. Common features are abrupt onset with fever, headache, prostration, muscular pains, cough and nasal symptoms in the absence of markedly abnormal physical signs. During interepidemic periods sporadic cases though presenting somewhat similar clinical pictures are difficult to diagnose with out aid from the laboratory.

A number of other infectious diseases may closely resemble influenza. Among these are undifferentiated acute upper respiratory infections, primary atypical pneumonia, paranasal sinusitis, abortive measles, dengue, Rift Valley fever, lymphocytic choriomeningitis and Venezuelan equine encephalomyelitis. In some instances influenza can be distinguished from these diseases only by laboratory procedures.

Infection with either influenza A or B virus may cause a wide variety of clinical pictures ranging from very mild to moderately severe illnesses. During epidemics subclinical or inapparent infections not associated with definite symptoms are common. Influenza A may lead to somewhat more marked symptoms than influenza B but the clinical findings do not distinguish one from the other.

An etiological diagnosis can be established only by laboratory procedures. The virus may be recovered from the upper respiratory tract during the acute phase of the illness. The virus cannot be recovered from the blood, cerebrospinal fluid or feces.

A specific antibody response to the infecting virus may be demonstrated with appropriate serum specimens by various immunological techniques. Complement fixation, virus neutralization and hemagglutination inhibition procedures can all yield satisfactory results. Two specimens of serum are needed from each patient: one should be obtained less than five days after onset, the other two or three weeks later. Before throat washings or serum specimens are obtained the laboratory which is to carry out the tests should be consulted.

**Prognosis** In previously healthy children or adults the prognosis is excellent and an uneventful recovery may be anticipated in the great majority of patients. In undernourished or debilitated persons, those with chronic diseases or persons of advanced age the prognosis may not be as good. Such patients appear to be more liable to develop secondary bacterial infections of the respiratory tract and pneumonia may arise. Under these circumstances the prognosis becomes that usually associated with the particular bacterial infection. Antimicrobial therapy appears to be about as effective in controlling secondary bacterial infection as associated with influenza as in similar infections in the absence of the viral disease.

In the rare instances in which the virus invades the lungs, antimicrobial therapy is of no avail.

**Prognosis** In previously healthy children vaccines capable of inducing temporarily increased resistance to influenza A and B have been developed and gradually improved. The currently available vaccines contain a number of strains of both viruses which have been inactivated and to some degree purified from the allantoic fluid of infected chick embryos. Subcutaneous or intramuscular injection of such a vaccine usually results in the production of antibodies against the viruses in the vaccine. An increase in the antibody levels of the serum begins about a week after injection of the vaccine and the maximal antibody response is present at about two weeks. After another month or six weeks the increased antibody levels gradually decline. To a considerable extent the degree of increase in resistance to infection with either influenza A or B virus is directly correlated with the serum antibody level.

Vaccination leads in general to reduced susceptibility to infection for some months; estimates range from two to twelve months. Protection is not complete and vaccinated persons can still contract the disease. Avail-

able vaccines although capable of diminishing the likelihood of infection are effective for a relatively short period. As a consequence they are most useful when given shortly before an epidemic. Predictions on the occurrence of epidemics are notably unreliable. Influenza virus vaccines possess toxic properties and if a sufficient quantity is injected may lead to unpleasant symptoms especially in children. In addition they contain some chick embryo material which is antigenic. This may induce sensitization or in rare instances lead to serious reactions in persons hypersensitive to egg products.

**Treatment.** Effective chemotherapy against the viral infection has not yet been developed. Supportive and symptomatic treatment similar to that used in other acute upper respiratory infections provides some relief. During the febrile period the patient should remain in bed. Large quantities of fluid should be taken and the diet should be liquid or light. Acetylsalicylic acid 0.3 to 1.0 gm and codeine 0.016 to 0.032 gm are the drugs most commonly employed. Barbiturates may be used to control sleeplessness. Sulfonamide drugs and penicillin even in large doses are ineffective. Similarly the tetracyclines and chloramphenicol do not favorably affect the course of the disease. The injection of influenza virus vaccine after the disease has appeared is not beneficial and may increase symptoms.

Because secondary bacterial infections occur in only a small proportion of patients it is in general unwise to attempt to prevent their development with antimicrobial drugs. However when definite bacterial infection does develop appropriate chemotherapy should be instituted and carried out as it would be in the absence of the viral infection. This is especially important when bacterial pneumonia appears.

## Dengue

**Definition.** Dengue is an acute febrile nonfatal disease of viral etiology characterized by localized and generalized aches and pains, prostration, exanthema, lymphadenopathy and leukopenia. **Transmission** is by bite of mosquitoes specifically of genus *Aedes*. Two antigenically distinct types of dengue virus are known which belong to the family of group B arthropod borne (Arbor) viruses.

**Etiology.** Dengue virus can be isolated from patients' blood during the febrile phase of the disease. Serum obtained on the first day of fever contains about 1,000,000 infectious doses per ml. The virus can be inactivated by heating at 56°C for thirty minutes by ultraviolet light or by treatment with 0.05 per cent formalin. Inactivation by these methods also destroys the immunogenic capacity of the virus. Infectivity can be preserved for many years by freezing or lyophilizing. The viral elementary body, assuming that it is spherical, has a diameter of 17 to 25 mμ.

During World War II Sabin and Schlesinger in the United States and Hotta in Japan succeeded in adapting dengue virus to mice. This opened the way to intensive studies on the properties of dengue virus and its relationship to other agents. When first isolated from the blood of sick patients, the virus is usually not pathogenic for laboratory animals. In the course of serial intracerebral passages in baby mice, the virus undergoes progressive modifications. This manifests itself in the form of gradually emerging virulence—first for suckling mice only, later also for adult mice—and the ability to multiply in chick embryos and in monkey kidney tissue cultures. The modified virus causes fatal encephalomyelitis in mice. Adaptation of the virus to the mouse or chick embryo is associated with attenuation of its pathogenicity for man. Human beings inoculated with modified virus experience none of the debilitating signs and symptoms of dengue but they develop a typical rash and subsequently are immune to infection with unmodified virus of the same serological type.

The existence of two serological types (I and II) was first discovered in cross-immunity tests in human volunteers, later verified by neutralization tests in mice. Complement fixing and hemagglutinating antigens can be extracted from infected tissues. Serological tests with such antigens have revealed cross-reactions not only between the two types of dengue virus but also between these and other members of the group B arthropod borne ("Arbor") viruses (such as yellow fever, Japanese B, St. Louis encephalitis, West Nile and others).

**Incidence and Epidemiology.** Dengue has been known as an epidemic disease since the late eighteenth century. Since 1920 very extensive epidemics have occurred in the United States (Gulf Coast), Greece, Australia and Japan. In such epidemics the disease may affect 40 to 80 per cent of the

population of cities. Epidemics of such proportions are undoubtedly due to the importation of the virus into a nonimmune population at a time when suitable insect vectors abound. In other areas, notably the Southwest Pacific Islands, Queensland and New Guinea, Indonesia, the Philippines, portions of India, Malaya, Burma and Indochina, and perhaps sections of Africa, the disease is endemic. Newcomers to endemic areas incur a high risk of acquiring the disease.

Infection is transmitted from man to man by the bite of mosquitoes of the genus *Aedes*. Species definitely incriminated as vectors are *Aedes aegypti*, *Aedes albopictus*, *Aedes scutellaris* and *Aedes polynesiensis*. Marks. After engorgement with infectious blood, an extrinsic incubation period of eight to fourteen days is required before *A. aegypti* can transmit the virus. The bite of a single infected mosquito is enough to produce the disease, and the insects once infected remain capable of transmitting the virus for the rest of their lives. Inapparent infection with dengue virus can be produced in monkeys, and these animals may play a role as intermediate or alternate hosts. Recent findings by Smith in Malaya suggest on the basis of serological evidence that monkeys and certain other tree-living animals may be intermediate hosts to the virus, and that *A. albopictus* may be responsible for transmission among these species as well as for endemic persistence of virus in rural areas. Spread from these areas to urban centers leading to localized outbreaks seems to be precipitated by invasion by *A. aegypti*. The latter being domestic in its habits is probably responsible for large-scale epidemics. The possibility that *Haemagogus* mosquitoes may play a role in the transmission of "jungle dengue" has also been suggested.

**Morbid Anatomy.** Dengue is a nonfatal disease; it is dubious whether the reported postmortem findings in alleged uncomplicated cases were typical of dengue. Sabin found that tissue obtained by biopsy of cutaneous eruptions showed marked vasculitis with endothelial swelling and perivascular edema and infiltration with mononuclear cells.

**Symptoms.** The incubation period averages five to eight days. The onset is usually sudden with a sharp rise in temperature associated with chills, excruciating head-ache, retro-ocular pain—especially on movement of the eyeballs—photophobia, back-ache, pain in muscles and joints. At this time there is no distinct rash, but the face

is flushed and the skin may be diffusely mottled. Fever persists for five to six days at 103 to 105 F. Occasionally the temperature returns to normal or nearly normal about the third day, then rises again, thus giving the classic (but rare) saddle-back fever curve. In addition to the symptoms already listed, others referable to various organ systems are frequently encountered, e.g., altered taste, sensations of sore throat, marked anorexia and constipation, colicky pain, abdominal tenderness, hyperesthesia of the skin and drawing pain in the inguinal region and testicles. The most constant and characteristic symptoms, however, are headache, pain on movement of the eyeballs, photophobia and the severe generalized aches and pains which have earned the disease the name "breakbone fever." The marked discomfort combined with a tendency to be depressed and extremely weak causes the patient to take a very dim view of his chances of recovery.

Although absence of rashes has been observed in various proportions of patients in spontaneous dengue epidemics, the experimentally produced disease is almost invariably associated with an intense maculopapular eruption spreading over the entire body. This appears usually about the third or fourth day of fever. The rash fades on pressure. Later at defervescence, nonfading petechial hemorrhages may be superimposed at certain sites, e.g., on the insteps, in skin folds, in areas exposed to pressure from clothing or bandages and on the oral mucosa. Lymph nodes are often enlarged but are not tender.

The disease is associated with marked leukopenia. As a rule, the total leukocyte count decreases at the onset of fever and remains at 2000 to 3000 per cu mm during the acute phase. Initially there are lymphopenia and a marked increase in immature neutrophilic leukocytes. Toward the end of the febrile phase, there may be a change in the direction of relative lymphocytosis.

In epidemics, patients are often seen with relatively mild disease, shorter in duration than the typical syndrome and not associated with rash. On the basis of experimental findings, it has been suggested that such mild episodes may be due to second infections of persons partially immune as a result of previous infection with an immunologically distinct strain of virus.

**Immunity.** The existence of immunity to reinfection was inferred years ago from epidemiological evidence, e.g., from the differences in incidence of dengue among

able vaccines although capable of diminishing the likelihood of infection are effective for a relatively short period. As a consequence they are most useful when given shortly before an epidemic. Predictions on the occurrence of epidemics are notably unreliable. Influenza virus vaccines possess toxic properties and if a sufficient quantity is injected may lead to unpleasant symptoms especially in children. In addition they contain some chick embryo material which is antigenic. This may induce sensitization or in rare instances lead to serious reactions in persons hypersensitive to egg products.

**Treatment** Effective chemotherapy against the viral infection has not yet been developed. Supportive and symptomatic treatment similar to that used in other acute upper respiratory infections provides some relief. During the febrile period the patient should remain in bed. Large quantities of fluid should be taken and the diet should be liquid or light. Acetylsalicylic acid 0.3 to 1.0 gm and codeine 0.016 to 0.032 gm are the drugs most commonly employed. Barbiturates may be used to control sleeplessness. Sulfonamide drugs and penicillin even in large doses are ineffective. Similarly the tetracyclines and chloramphenicol do not favorably affect the course of the disease. The injection of influenza virus vaccine after the disease has appeared is not beneficial and may increase symptoms.

Because secondary bacterial infections occur in only a small proportion of patients it is in general unwise to attempt to prevent their development with antimicrobial drugs. However when definite bacterial infection does develop appropriate chemotherapy should be instituted and carried out as it would be in the absence of the viral infection. This is especially important when bacterial pneumonia appears.

## Dengue

**Definition** Dengue is an acute febrile nonfatal disease of viral etiology characterized by localized and generalized aches and pains, prostration, exanthema, lymphadenopathy and leukopenia. Transmission is by bite of mosquitoes specifically of genus *Aedes*. Two antigenically distinct types of dengue virus are known which belong to the family of group II arthropod borne ("Arbor") viruses.

**Etiology** Dengue virus can be isolated from patients' blood during the febrile phase of the disease. Serum obtained on the first day of fever contains about 1,000,000 infectious doses per ml. The virus can be inactivated by heating at 56° C for thirty minutes by ultraviolet light or by treatment with 0.05 per cent formalin. Inactivation by these methods also destroys the immunogenic capacity of the virus. Infectivity can be preserved for many years by freezing or lyophilizing. The viral elementary body assuming that it is spherical has a diameter of 17 to 25 mμ.

During World War II Sabin and Schlesinger in the United States and Hotta in Japan succeeded in adapting dengue virus to mice. This opened the way to intensive studies on the properties of dengue virus and its relationship to other agents. When first isolated from the blood of sick patients the virus is usually not pathogenic for laboratory animals. In the course of serial intracerebral passages in baby mice the virus undergoes progressive modifications. This manifests itself in the form of gradually emerging virulence—first for suckling mice only later also for adult mice—and the ability to multiply in chick embryos and in monkey kidney tissue cultures. The modified virus causes fatal encephalomyelitis in mice. Adaptation of the virus to the mouse or chick embryo is associated with attenuation of its pathogenicity for man. Human beings inoculated with modified virus experience none of the debilitating signs and symptoms of dengue but they develop a typical rash and subsequently are immune to infection with unmodified virus of the same serological type.

The existence of two serological types (I and II) was first discovered in cross-immunity tests in human volunteers later verified by neutralization tests in mice. Complement fixing and hemagglutinating antigens can be extracted from infected tissues. Serological tests with such antigens have revealed cross reactions not only between the two types of dengue virus but also between these and other members of the group II arthropod borne ("Arbor") viruses (such as yellow fever, Japanese B. St. Louis encephalitis, West Nile and others).

**Incidence and Epidemiology** Dengue has been known as an epidemic disease since the late eighteenth century. Since 1920 very extensive epidemics have occurred in the United States (Gulf Coast), Greece, Australia and Japan. In such epidemics the disease may affect 40 to 80 per cent of the

several times a day particularly the short hair of the neck and all ticks removed. The feeding or attached tick is removed with some difficulty the best method being to apply some irritant such as turpentine, iodine or acetone. Then the tick can be teased out of the skin by inserting a needle between the mouth parts. Should the mouth parts be left in the skin a small shallow indolent ulcer is likely to develop.

The virus is transmitted transovarially and consequently the infection is self-perpetuating in the tick. No animal host has as yet been demonstrated. It is easy to infect the hamster or newborn mice with blood from a patient.

No one has ever been reported to have had the disease twice.

**Morbid Anatomy Pathological Physiology.** Only one death has been reported consequently little is known about pathological changes in the tissues. Like dengue however the disease causes a definite reduction in the leukocyte count. Counts lower than 2000 per cu mm are frequently recorded the low point usually occurring during the second attack. All of the leukocytes are reduced in absolute numbers except the monocytes. There is a marked increase in the band forms. Hematological recovery follows clinical recovery by four to seven days.

**Symptoms and Clinical Course.** The onset is sudden with chilly sensations and mild photophobia. This is quickly followed by

generalized aching especially in the muscle and tendon insertions around the joints. The other prominent features of this aching consist of headache, deep ocular pain and backache particularly in the lumbar region. Anorexia and nausea are common. Vomiting occurs in children. The first attack lasts approximately two days followed by a complete remission of all signs and symptoms for about the same length of time. The second attack usually lasts somewhat longer than the first. Either episode may be more severe than the other. Although the usual pattern is for an attack and the remission to last approximately two days each variations of one to four days do occur. Third attacks have been reported. A single episode lasting five to seven days is likewise possible. While disappearance of symptoms occurs rapidly at the end of the second attack the patient usually has a period of four to five days of mild lassitude. Figure 1 is typical of most of the cases recognized in the western states.

**Diagnosis.** The diagnosis is made on the basis of the following criteria: (1) A history of having been bitten by a tick or having been in a tick infested area four to six days prior to onset. (2) A fever curve and symptoms identical with dengue. The temperature rises rapidly to 102° to 104° F and occasionally to 105° F. During the remission it is frequently subnormal. (3) Absence of physical findings other than fever with a corresponding increase in pulse rate.

FIG 1 Colorado tick fever

native soldiers and recently arrived American troops stationed together in the Philippine Islands. Experimentally infected volunteers retain solid immunity to reinfection with homotypic virus for years but early reinfection with a heterologous strain may lead to mild second disease (see above). In line with this type specific neutralizing antibodies persist in the serum for many years while cross neutralization of heterologous strains is absent or weak.

**Diagnosis** The disease is easily diagnosed on clinical grounds when it is fully developed. Dengue should always be suspected when febrile illnesses of the type described occur in suitable epidemiological environments. Specific differentiation from other febrile illnesses with similar symptoms rests on serological confirmation. The neutralization test is type specific in primary infection while complement fixation and hemagglutination-inhibition reactions cross with other group B arbovirus antigens. The specificity of any serological response may be doubted however in inhabitants of an area in which more than one group B arbovirus are endemic or in persons previously vaccinated against yellow fever. Under these conditions previous sensitization may lead to a broad group specific anamnestic antibody response which extends even to neutralizing antibody.

**Prognosis** Uncomplicated dengue is not fatal but complete recovery may take several weeks. Convalescence is characterized by prolonged weakness and sometimes by mental depression.

**Treatment and Prevention** Treatment of the acute disease is entirely nonspecific and should include absolute bed rest, maintenance of fluid and electrolyte balance and alleviation of discomfort. Acetylsalicylic acid 0.3 to 0.6 gm. alone or in suitable combination with phenacetin and caffeine should be given every three to four hours (salicylates may produce marked aberrations from the typical fever chart). Severe pains may necessitate oral or subcutaneous administration of codeine sulfate 30 to 60 mg. Other therapeutic measures should be designed to keep the patient as comfortable as possible. Complications should be anticipated, recognized and treated as indicated. Resumption of normal activities should not be rushed; a two week period of convalescence is desirable and often needed.

The most practicable method of prevention is eradication of mosquito vectors. Vaccines prepared from infected mouse brain or chick embryo have been effective in experiments on human volunteers and

their use may be considered under conditions of critical need.

### Colorado Tick Fever

**Definition and Etiology** Colorado tick fever is a distinct disease entity of viral etiology transmitted by ticks. It is clinically indistinguishable from dengue except for the absence of a rash.

**Incidence, Epidemiology and Prevention** The disease is unfortunately named since it has been reported in all the western states in which the wood tick *Dermacentor andersoni* is found. In Colorado it is by far the most common of the tick-borne diseases, probably outnumbering Rocky Mountain spotted fever 100 to 1. Although it has never been reported on the eastern seaboard, the virus has been isolated from Long Island dog ticks *Dermacentor variabilis*. Colorado tick fever therefore is probably not confined to the west but like Rocky Mountain spotted fever will be found in other parts of the United States.

The disease occurs in the spring and early summer when the ticks are active. Invariably the victim has been in a tick-infested area four to six days prior to onset. In most cases either the patient will have found the feeding tick prior to the illness or a careful search at the time of onset will demonstrate it. The person involved is not aware of the presence of this arthropod since the bite is painless. Persons who visit in the mountains particularly if they walk through tall grass and low shrubs are likely to pick up one or more ticks. The entire body should be thoroughly inspected

several times a day particularly the short hair of the neck and all ticks removed. The feeding or attached tick is removed with some difficulty, the best method being to apply some irritant such as turpentine, iodine or acetone. Then the tick can be teased out of the skin by inserting a needle between the mouth parts. Should the mouth parts be left in the skin a small shallow indolent ulcer is likely to develop.

The virus is transmitted transovarially and consequently the infection is self-perpetuating in the tick. No animal host has as yet been demonstrated. It is easy to infect the hamster or newborn mice with blood from a patient.

No one has ever been reported to have had the disease twice.

**Morbid Anatomy, Pathological Physiology.** Only one death has been reported consequently little is known about pathological changes in the tissues. Like dengue however the disease causes a definite reduction in the leukocyte count. Counts lower than 2000 per cu mm are frequently recorded the low point usually occurring during the second attack. All of the leukocytes are reduced in absolute numbers except the monocytes. There is a marked increase in the band forms. Hematological recovery follows clinical recovery by four to seven days.

**Symptoms and Clinical Course.** The onset is sudden with chills, sensations and mild photophobia. This is quickly followed by

generalized aching especially in the muscle and tendon insertions around the joints. The other prominent features of this aching consist of headache, deep ocular pain and backache particularly in the lumbar region. Anorexia and nausea are common. Vomiting occurs in children. The first attack lasts approximately two days followed by a complete remission of all signs and symptoms for about the same length of time. The second attack usually lasts somewhat longer than the first. Either episode may be more severe than the other. Although the usual pattern is for an attack and the remission to last approximately two days each variations of one to four days do occur. Third attacks have been reported. A single episode lasting five to seven days is likewise possible. While disappearance of symptoms occurs rapidly at the end of the second attack the patient usually has a period of four to five days of mild lassitude. Figure 1 is typical of most of the cases recognized in the western states.

**Diagnosis.** The diagnosis is made on the basis of the following criteria: (1) A history of having been bitten by a tick or having been in a tick infested area four to six days prior to onset. (2) A fever curve and symptoms identical with dengue. The temperature rises rapidly to 102° to 104° F and occasionally to 105° F. During the remission it is frequently subnormal. (3) Absence of physical findings other than fever with a corresponding increase in pulse rate.

FIG. 1 Colorado tick fever

slight erythema of the skin and conjunctival injection (4) A reduced leukocyte count with an increase in immature forms (5) Other confirmatory laboratory tests usually unnecessary in the typical case

Complement fixation tests during the acute phase and three weeks following recovery may be a useful procedure The first test should be negative and the second positive Injection intraperitoneally or intracerebrally into baby mice or baby hamsters of blood serum obtained during any phase of the disease will cause the death of these animals while neutralization of the virus with immune serum results in survival

Care must be exercised not to confuse Colorado tick fever with the much more severe and frequently fatal Rocky Mountain spotted fever especially since specific treatment is available for the latter The difference in severity between the two is most helpful while the rash of Pocky Mountain spotted fever will always differentiate the two There is no disease in the United States with which typical Colorado tick fever should be confused except dengue The mode of spread and the frequent presence of a rash in dengue suffice to differentiate them Colorado tick fever is not a tick borne disease since neither disease gives an immunity to the other although each confers immunity to itself

**Prognosis** The prognosis is excellent Complications or sequelae have been infrequently observed The virus is always found in the cerebrospinal fluid No increase in pressure or other abnormalities of the fluid have been observed except in the occasional patient who develops encephalitis

**Treatment** Treatment is symptomatic Acetylsalicylic acid in standard doses is usually sufficient to reduce the fever and aching There is no evidence that any of the available antimicrobial drugs is of value

## Yellow Fever

**Definition** Yellow fever is an acute viral disease characterized by sudden onset prostration moderately high fever a pulse rate slow in relation to temperature and when severe by vomiting of altered blood albuminuria and jaundice It is endemic in the tropical rain forests of Africa and South America in the past summer epidemics have been widespread in the temperate zone There are two epidemiological types of the disease When the virus is transmitted from man to man by the domestic mosquito *Aedes aegypti* it is called urban yellow fever but when it occurs in a forest environment and is transmitted to man by some forest mosquito usually in the absence of *A. aegypti* it is called sylvan (or jungle) yellow fever

**Etiology and Epidemiology** Yellow fever virus is a group B arbovirus according to Casals new serological classification of viruses it is small about 17 to 25 m $\mu$  in diameter In nature the virus is pantropic in that it has viscerotropic and neurotropic characteristics Viscerotropism enables the virus to attack the liver kidneys and heart while neurotropism permits it to infect cells of the central nervous system The virus becomes more neurotropic and loses its viscerotropism almost entirely during long continued brain to brain passage through mice Prolonged passage of the virus in tissue culture has produced an attenuated strain 17D suitable for use as vaccine

Man is universally susceptible to the virus and the characteristic symptoms and lesions of yellow fever in man are due to its viscerotropism severe disease being the exception rather than the rule The rhesus monkey while no more susceptible to infection by the virus is much more likely to die of the disease Albino mice especially of the Swiss strain are highly susceptible to the neurotropic element of pantropic strains of the virus provided they are inoculated by the intracerebral route

In urban yellow fever the *A. aegypti* mosquito transmits the virus by biting a human host during his initial three-day period of viremia and later biting a susceptible person An extrinsic incubation

period of nine to twelve days must elapse before the mosquito becomes infectious by bite

In sylvan yellow fever man acquires his infection through the bite of some mosquito other than *A. aegypti*. In South America the virus has been isolated from wild caught mosquitoes of the genus *Haemagogus* and from *Aedes leucocelaenus*. In Africa it has been obtained from wild caught *Aedes simpsoni* and *A. africanus*. The more important of these vectors *Haemagogus* and *A. africanus* inhabit chiefly the forest canopy which is also the habitat of the monkeys which are most frequently infected in nature. The exact role of monkeys in the epidemiology of sylvan yellow fever has not been elucidated.

Since 1934 no large epidemics of urban yellow fever have been reported from the Western Hemisphere and the few small *A. aegypti* transmitted epidemics which have occurred have been secondary to sylvan yellow fever. In Africa in areas contiguous to the rain forest areas where sylvan yellow fever is endemic there are still frequent epidemics of urban yellow fever. An important epidemic occurred in Nigeria in 1946. Beginning in 1948 in Panama an epidemic wave of sylvan yellow fever has been spreading northward through the forests of Central America.

There is no evidence that yellow fever has ever been present in the Orient.

**Morbid Anatomy** Yellow fever produces characteristic lesions in the liver of man. There is necrosis and necrobiosis of the parenchymal cells most evident in the mid zones of the lobules with normal or much less involved cells around the central and portal veins. The necrosis is scattered and irregular rather than massive and uniform. Scattered among the necrotic cells are Councilman bodies parenchymal cells which have undergone eosinophilic hyaline necrosis. There are also fatty changes in the parenchymal cells. The liver lobules are not collapsed.

**Clinical Manifestations** The great majority of attacks of yellow fever are mild and show few of the classic symptoms. Not infrequently the only symptoms are low fever and headache both of short duration.

The incubation period is from three to six days. The onset is sudden often with a chill and without prodromal symptoms. The first stage of the disease which lasts about three days is the *period of infection*. The symptoms are fever severe headache backache pain in the legs and prostration. The face is flushed and the eyes are in

jected there is photophobia. The tongue is bright red at the tip and edges. There is no jaundice at the onset of the illness. The temperature rises abruptly to about 104° F sometimes higher. The pulse may rise to 90 or 100 initially only to become increasingly slow in relation to the temperature (Faget's sign). The pulse is full and strong during this stage. Nausea and vomiting are the rule as are epigastric distress and tenderness. Constipation is to be expected. A progressive leukopenia sometimes pronounced has frequently been observed early in the disease. The sudden development of intense albuminuria about the third or fourth day is characteristic.

After a short remission the *period of intoxication* begins about the fourth day. The remission in fever is often indefinite or absent and it may be accompanied by a deceptive temporary improvement. In this period lassitude and depression may replace restlessness and agitation. Headache may diminish and jaundice gradually develops. While jaundice is always present in severe cases it is usually not so marked as the name of the disease would indicate. The gums are swollen and bleed easily either spontaneously or when pressed. The nose may bleed. There may be petechiae in the skin. Hemorrhages from the stomach, intestine or uterus or subcutaneously may be massive. The pulse rate falls progressively and may go below 50 per minute. Even in otherwise mild attacks there may be marked dilatation of the heart and low blood pressure as evidence of myocardial damage. Vomiting may be frequent and distressing and the vomitus in this stage usually contains altered blood. The amount of albumin in the urine rises often to 3 to 5 gm per liter sometimes much higher. Fatal cases often exhibit hiccup, copious vomiting of altered blood, tarry stools and anuria. Coma may last two or three days or death may be immediately preceded by a short period of wild delirium. Death occurs most frequently from the sixth to the ninth day.

When there is recovery from a severe case the temperature is likely to reach normal by the seventh or eighth day. Convalescence begins then and progresses rapidly to complete recovery with rapid disappearance of the albuminuria. Relapses do not occur and there are no sequelae. Complications are rare. A life long immunity follows the attack whether it be mild or severe.

A peculiarity of yellow fever is the great variation in the degree to which different

organs are affected. With much renal involvement there may be no cardiac symptoms and vice versa. In mild and moderate cases there is little or no albuminuria, jaundice or hemorrhage.

**Diagnosis** In a severe febrile illness with black vomit, intense albuminuria and jaundice, yellow fever must be suspected. Diseases which must be differentiated from severe yellow fever are infectious and serum hepatitis, acute yellow atrophy of the liver, carbon tetrachloride poisoning, other jaundices and even malaria. In mild cases of yellow fever which have been confused with dengue and influenza, clinical diagnosis is notoriously inaccurate. The necessary laboratory diagnostic procedures are highly specialized. These are two: the isolation of the virus in mice or rhesus monkeys and yellow fever neutralization tests on paired acute phase and convalescent serums.

For postmortem diagnosis, specimens of liver and other tissues should be preserved in 10 per cent formalin for histological examination.

**Prognosis** Early in the disease the prognosis should always be guarded, since sudden changes for the worse are not uncommon. If early symptoms are mild, rapid recovery is probable, though some severe cases will end favorably. Hiccup, copious black vomit, melena and anuria require a very grave prognosis.

The overall average case fatality rate is less than 10 per cent, and rates of less than 5 per cent have been observed in epidemics involving completely susceptible populations. Rates as high as 85 per cent have been observed, but they are most exceptional. Even the often cited 50 per cent rate is false, because large numbers of mild cases have been missed.

**Treatment** There is no specific treatment. A patient should be moved as little as possible and should be kept quiet in bed. The severe headache and body aches may require relief with an analgesic. The heart should be watched carefully throughout the illness and into early convalescence.

Water should be given in adequate amounts parenterally if necessary. Easily assimilated food should be given to the extent which the patient will tolerate. Citrus fruit juices ad lib are a time honored prescription, but milk in moderate quantities would appear to be much more useful to a damaged liver. When vomiting has ceased and the temperature is down, full diet may be given. Full activity should be resumed only gradually.

**Prevention** If a case of yellow fever is treated in a place in which vector mosquitoes exist, the patient must be kept under a bed net or in a mosquito proof room during the first four days of his illness.

Vaccination is essential for persons who intend to visit yellow fever endemic areas and for the people resident in such areas. Two strains of living virus have been used extensively for human vaccination. The 17D vaccine is prepared in chick embryos and is given by subcutaneous inoculation. At the Pasteur Institute of Dakar, the technique of vaccination by scarification of the skin was developed using the neurotropic French strain suspended in gum arabic solution. With either strain, an effective immunity to yellow fever is regularly produced. Severe reactions to the Dakar type of vaccine seem to be more frequent than are reactions to 17D. Vaccination ordinarily gives protection in a week, and the consequent immunity has been shown to last at least six years. Communities infested with *Aedes aegypti* should protect themselves by exterminating that mosquito, making use of the efficient methods now available. An urban epidemic can best be stopped by mass vaccination of the population combined with a DDT spraying campaign.

## Measles

(Morbilli: Rubeola)

**Definition** Measles is an extremely contagious febrile disease of high morbidity characterized by rash and catarrhal inflammation of the eyes and respiratory tract. It is principally a benign disease of children but may afflict with equal frequency persons of any age not previously attacked by its virus.

**History** Although exanthems comparable to measles were described in Arabian writings as early as the tenth century, Sydenham in the seventeenth

century was probably the first to distinguish the disease clearly from other infections. The infectious nature of measles was first conclusively demonstrated by Hektoen in 1905 in man to man transmission experiments. Convalescent serum was shown to be effective in the prevention of the disease by Nicolle and Conseil in 1918.

**Etiology** Measles is caused by a virus of narrow host range which induces manifest disease only in man and monkeys. Until recently the demonstration of measles virus has been definitively dependent upon inoculation of human subjects or monkeys. The discovery (Enders and Peebles 1954) that the virus is propagable in a variety of tissue cultures has received abundant confirmation. This convenient method has permitted recovery of virus from the blood and throat washings of patients with typical measles and the demonstration of specific antibody response to infection. This significant laboratory advance now provides for the first time techniques for the specific diagnosis of measles. Isolation of the virus and demonstration of antibody are still the province of the special virus laboratory; however, and entail techniques which are not yet generally available.

It is to be expected that knowledge of the epidemiology, immunology and pathogenesis of measles will be expanded rapidly now that the etiological agent may be manipulated with relative ease.

**Incidence and Epidemiology** Measles is a disease of cosmopolitan distribution, endemic in all but isolated populations. It may occur at any time of the year but most outbreaks are in the late winter and early spring. The disease recurs in epidemic cycles at two to three year intervals in most civilized communities which have been studied. This epidemic periodicity is best explained as a result of the introduction of new susceptibles into the population by birth or ingress from other areas. When the proportion of nonimmunes reaches a certain crucial concentration, disease and coincident dissemination of virus may occur to produce an epidemic. It is likely that virus is introduced from sources external to the involved population, probably by incoming susceptibles; there is no solid evidence of subclinical infection or a post-infection carrier state with unmodified measles to suggest local persistence of virus in interepidemic periods. Isolated communities such as the Faroe Islands (Panum) are infrequently attacked by measles at which times manifest illness appears in virtually all persons not previously infected. In Greenland, a country not known to have

been invaded previously by the disease, a recent epidemic resulted in overt measles in 99.9 per cent of the indigenous population (Christiansen and others).

Throughout most of the world, measles is a disease of children; most adults possess acquired immunity. Morbidity and mortality rates do not appear to be influenced by sex or race. Case fatality rates are highest in children less than five years of age and are also relatively high in the aged. Congenital infection has occurred.

There is no evidence that the virus may vary in virulence in nature. The oft-cited and notorious virulence of the disease in primitive, isolated or crowded populations may be explained as a corollary of (1) more prevalent infection of feeble and aged adults, (2) poor environmental conditions, (3) inadequate medical care, and (4) secondary bacterial infections. Because measles virus *per se* rarely induces fatal disease, it is evident that fatalities attributable to measles may vary in incidence according to the prevalence of bacterial pathogens and the resistance of the population to their presence.

**Communicability** Measles is one of the most contagious of infections. Demonstration of virus in nasopharyngeal secretions is in accord with epidemiological evidence that infection is disseminated and acquired by the respiratory tract. Close physical proximity or direct person to person contact is the usual requisite for infection, but third person transfer has occurred.

**Immunity** An unmodified attack of measles usually confers lifelong immunity. Able observers have described apparently authentic instances of second or even multiple infections. Definitive proof of recurrent infection with measles virus is lacking, however, because specific diagnostic laboratory tests have only recently become available. Detailed study of a family subject to recurrent attacks suggests an hereditary defect in the capacity to develop immunity in certain cases. One such patient was found to be capable of antibody formation and electrophoretic analysis of the serum showed no deficit of gamma globulin. Temporary immunity may be passively acquired by receipt of convalescent serum or gamma globulin derived from the pooled sera of human adults (see Treatment). Humoral antibody is demonstrable in patients convalescent from gamma globulin-modified measles. The low incidence of measles in early infancy (first six months) is attributed to transient protection by placentally transferred maternal antibody.

**Morbid Anatomy** Pathological changes in fatal measles usually represent the compound effect of viral and secondary bacterial infection. Bronchopneumonia is almost invariably present; it is most frequently interstitial but may be lobular with purulent exudate within the alveoli. More representative of the pathology of the uncomplicated viral disease are changes within the tonsillar, nasopharyngeal and appendiceal tissue removed during the prodrome. These changes consist of subepithelial round cell infiltration and the presence of large multinucleated giant cells (Warthin). The latter are so characteristic that skilled pathologists have predicted the development of rash from their presence in surgical specimens. The lesions clinically apparent as Koplik's spots derive from inflammatory mononuclear cell infiltration of buccal submucous glands and necrosis of focal vesicular lesions of the mucosa. Rash is the result of proliferation of capillary endothelial cells in the corium and the coincident exudation of serum and occasionally erythrocytes into the epidermis.

**Pathological Physiology** No consistent or characteristic aberrations in physiology are observed with measles. The transient hemoconcentration and albuminuria found with other febrile diseases may occur. A normal total leukocyte count or leukopenia is observed throughout the febrile period. Initially the leukopenia is occasioned by a decline in lymphocytes on the first day of fever; subsequently granulocytopenia ensues as well. The incubation period is characterized by neutrophilia and convalescence by a relative lymphocytosis. A false positive serological test for syphilis may be observed.

**Hormone-like Effects of Measles Infection** Several striking physiological effects of measles, although poorly understood, mimic the influence of corticotropin or the adrenal corticosteroids. These are transient suppression of the tuberculin reaction, improvement in eczema and allergic asthma, delay in wound healing, and the induction of remissions in leukemia, Hodgkin's disease and lipid nephrosis. Whether these effects are directly attributable to the virus or are hormonally mediated is not known.

**Symptoms** Following an incubation period which averages eleven days, measles becomes clinically manifest with symptoms of fever, malaise, myalgia and headache. Within hours ocular symptoms of photophobia and burning pain are evidenced by conjunctival injection, tearing and exudate in the conjunctival sac. Concomitantly or

soon thereafter catarrhal inflammation of the respiratory tract is manifested by sneezing, coughing and nasal discharge. Less commonly hoarseness and aphonia may reflect laryngeal involvement. In this prodromal stage of one to four days duration, petechial lesions of the palate and pharynx or tiny white spots on the buccal mucosa (Koplik's spots) may herald the appearance of skin rash. The white lesions described by Koplik characteristically occur lateral to the molar teeth and typically are mounted on red areolae of injected mucosa which may coalesce to form a diffuse red background. Not invariably present, they constitute a valuable if not pathognomonic diagnostic sign. The enanthem may involve other mucous membranes such as the vaginal lining. It may overlap the subsequent appearance of the cutaneous rash by one to three days. Rarely a transient erythematous exanthema may occur in the prodromal period.

The rash of measles follows the prodromal symptoms by two to four days, occasionally as late as seven days. It first appears behind the ears or on the face as a blotchy erythema, spreads downward to cover the trunk, and finally is manifest on the extremities. The hands and feet may escape involvement. Initially the eruption consists of discrete reddish brown macules which blanch with pressure. Subsequently these lesions become slightly elevated, tend to coalesce and may develop a hemorrhagic nonblanching component. The rash fades in the order of its appearance; its disappearance about five days after onset is attended by a fine powdery desquamation which spares the hands and feet. At its maximum the exanthema usually marks the termination of malaise and fever in the uncomplicated illness.

The fever of measles is commonly of the typhoidal, progressively rising type and falls by lysis. It persists for about six days and frequently reaches 103° F. In the adult, fever may follow rather than antedate the catarrhal symptoms. Throughout the febrile period, productive cough and auscultatory evidence of bronchiolitis may be evident. These manifestations may persist after defervescence and cough is often the last symptom to disappear. It is probable that bronchopulmonary symptomatology is an integral part of the primary viral infection. Roentgenographic evidence of pulmonary involvement is frequently seen in the uncomplicated disease in the absence of leukocytosis and obvious bacterial infection.

**Complications** It is difficult to distinguish between those complications directly at

tributable to the virus of measles and those resulting from secondary bacterial infections. The persistence or recurrence of fever and the occurrence of leukocytosis are presumptive evidence of the usual bacterial sequelae of otitis media or bronchopneumonia. Beta hemolytic streptococci are the most frequent secondary invaders but pneumococci or influenza bacilli may be implicated. The incidence of bacterial complications is increased by crowding, debility and the prevalence of bacterial pathogens in the population. Bacterially engendered sequelae may be unduly frequent in crowded contagious disease hospitals.

Serious complications directly related to the measles virus are rare. *Laryngitis* of sufficient severity to embarrass respiration has been observed and may warrant tracheotomy. *Electrocardiographic abnormalities* may be found in as many as 30 per cent of children but clinical evidence of cardiac disease is meager in such cases. *Abdominal pain* or *diarrhea* may be related to invasion of lymphoid tissue of the appendix or Peyer's patches. These symptoms may lead to unnecessary surgery before the appearance of the typical rash.

A rare (0.01 to 0.5 per cent) but serious consequence of measles is a demyelinating *encephalomyelitis* which may appear from one to fourteen days after the onset of infection. This complication is associated with a recurrence of fever and headache, vomiting and stiff neck. Stupor and occasionally convulsions follow. Localizing neurological symptoms may or may not be present. Death ensues in about 10 per cent of patients; about half of survivors suffer permanent residuals of varying severity (see chapter on Postinfection Encephalitis).

Other late sequelae of measles are thrombocytopenic purpura and exacerbation or activation of pre-existing pulmonary tuberculosis.

**Measles Modified by Antibody Administration** Attenuation of the natural disease by antibody prophylaxis may result in an illness of lessened severity comparable with the milder infection of the maternally immunized newborn. Fever alone may be observed but some degree of xanthema is usually apparent. Koplik's spots may not appear. In general the course is truncated and relatively uncomplicated.

**Diagnosis** The experienced layman can diagnose typical measles. The querulous, bleary-eyed child, his face blotched and his nose crusted with exudate, presents a characteristic if miserable picture as he breathes open mouthed between paroxysms

of sneezing and coughing. The severity of the catarrhal symptoms distinguishes the disease from other eruptive fevers. In the prodromal period the diagnosis should be suggested by (1) fever higher than that of the usual common cold, (2) known measles in the community and (3) Koplik's spots on the buccal mucosa.

FIG 2 ■ Koplik's spots in measles (Hecker, Trummel and Abt)

**Morbid Anatomy** Pathological changes in fatal measles usually represent the compound effect of viral and secondary bacterial infection. Bronchopneumonia is almost invariably present. It is most frequently interstitial but may be lobular with purulent exudate within the alveoli. More representative of the pathology of the uncomplicated viral disease are changes within the tonsillar nasopharyngeal and appendiceal tissue removed during the prodrome. These changes consist of subepithelial round cell infiltration and the presence of large multinucleated giant cells (Warthin). The latter are so characteristic that skilled pathologists have predicted the development of rash from their presence in surgical specimens. The lesions clinically apparent as Koplik's spots derive from inflammatory mononuclear cell infiltration of buccal submucous glands and necrosis of focal vesicular lesions of the mucosa. Rash is the result of proliferation of capillary endothelial cells in the corium and the coincident exudation of serum and occasionally erythrocytes into the epidermis.

**Pathological Physiology** No consistent or characteristic aberrations in physiology are observed with measles. The transient hemoconcentration and albuminuria found with other febrile diseases may occur. A normal total leukocyte count or leukopenia is observed throughout the febrile period. Initially the leukopenia is occasioned by a decline in lymphocytes on the first day of fever; subsequently, granulocytopenia ensues as well. The incubation period is characterized by neutrophilia and convalescence by a relative lymphocytosis. A false positive serological test for syphilis may be observed.

**Hormone like Effects of Measles Infection** Several striking physiological effects of measles although poorly understood mimic the influence of corticotropin or the adrenal corticosteroids. These are transient suppression of the tuberculin reaction, improvement in eczema and allergic asthma, delay in wound healing and the induction of remissions in leukemia, Hodgkin's disease and lipid nephrosis. Whether these effects are directly attributable to the virus or are hormonally mediated is not known.

**Symptoms** Following an incubation period which averages eleven days, measles becomes clinically manifest with symptoms of fever, malaise, myalgia and headache. Within hours, ocular symptoms of photophobia and burning pain are evidenced by conjunctival injection, tearing and exudate in the conjunctival sac. Concomitantly or

soon thereafter, catarrhal inflammation of the respiratory tract is manifested by sneezing, coughing and nasal discharge. Less commonly, hoarseness and aphonia may reflect laryngeal involvement. In this prodromal stage of one to four days duration, petechial lesions of the palate and pharynx or tiny white spots on the buccal mucosa (Koplik's spots) may herald the appearance of skin rash. The white lesions described by Koplik characteristically occur lateral to the molar teeth and typically are mounted on red areolae of injected mucosa which may coalesce to form a diffuse red background. Not invariably present, they constitute a valuable if not pathognomonic diagnostic sign. The enanthem may involve other mucous membranes such as the vaginal lining. It may overlap the subsequent appearance of the cutaneous rash by one to three days. Rarely, a transient erythematous exanthema may occur in the prodromal period.

The rash of measles follows the prodromal symptoms by two to four days, occasionally as late as seven days. It first appears behind the ears or on the face as a blotchy erythema, spreads downward to cover the trunk and finally is manifest on the extremities. The hands and feet may escape involvement. Initially, the eruption consists of discrete reddish brown macules which blanch with pressure. Subsequently, these lesions become slightly elevated, tend to coalesce and may develop a hemorrhagic nonblanching component. The rash fades in the order of its appearance; its disappearance about five days after onset is attended by a fine powdery desquamation which spares the hands and feet. At its maximum, the exanthema usually marks the termination of malaise and fever in the uncomplicated illness.

The fever of measles is commonly of the typhoidal, progressively rising type and falls by lysis. It persists for about six days and frequently reaches 103° F. In the adult, fever may follow rather than antedate the catarrhal symptoms. Throughout the febrile period, productive cough and auscultatory evidence of bronchiolitis may be evident. These manifestations may persist after defervescence, and cough is often the last symptom to disappear. It is probable that bronchopulmonary symptomatology is an integral part of the primary viral infection; roentgenographic evidence of pulmonary involvement is frequently seen in the uncomplicated disease in the absence of leukocytosis and obvious bacterial infection.

**Complications** It is difficult to distinguish between those complications directly at

beta hemolytic streptococcal infections. These circumstances include treatment of the chronically ill the very young or the aged and the treatment of patients under crowded conditions which foster the increase and dissemination of pathogenic bacteria as may occur in contagious disease hospitals. If careful observation of the patient is possible rational therapy is based on the prompt recognition and etiological definition of complications followed by initiation of the appropriate antimicrobial drug in proper dosage.

**Prevention** No vaccine is yet available for the production of effective active immunity (see Treatment).

## Rubella

(German Measles)

Rubella is an apparently benign but potentially malignant infection of children and young adults. This mild disease usually manifest only by its pale pink rash and posterior cervical lymphadenitis is now recognized as an important factor in the genesis of certain fetal abnormalities. Accordingly recognition and prevention of the disease are matters of far reaching consequence.

**Etiology** The causative agent of rubella is considered to be a virus largely on the basis of its filterability. Study of the virus has been limited by its restricted host range; its presence is demonstrable only by infection of humans or monkeys (Habel). The virus is detectable in both blood and nasopharyngeal washings soon after the rash appears and may be found in the blood two days before the eruption (Krugman

and others). Nasopharyngeal washings may retain infectivity for as long as two years when stored at  $-70^{\circ}\text{C}$  (Anderson 1950).

**Incidence and Epidemiology** Accurate information on the incidence of rubella is not available. The mildness and brevity of its clinical signs may confound the diagnosis and reporting of many instances of infection. Studies of the experimental disease lend support to prior clinical evidence that infection may occur without rash and indicate a further diagnostic pitfall. It can be said however that the disease is seen on every continent may occur in epidemic form and has its highest incidence in the early spring. The disease is less frequently acquired in childhood than measles as is attested by the fact that rubella is more common than measles in young adults. The higher incidence of infection in younger age groups in institutional outbreaks argues against a greater susceptibility of the adult. It is probable that rubella is spread by the respiratory route by close personal contact. The infection is contagious during the period of prodromal symptoms and the first day of rash. Like measles rubella rarely occurs in the first six months of life and is uncommon beyond the age of forty.

Immunity is lasting. Authenticated second attacks are rare and are virtually unprovable because of the nebulous nature of the clinical syndrome. Passive immunity of questionable efficacy may be conferred by the injection of gamma globulin from the scrums of patients convalescent from the disease (see Treatment). Rubella has no immunological relationship to measles.

**Morbid Anatomy** Death from uncomplicated rubella is unknown. Histological changes characteristic of the disease have not been demonstrated. The onset of disease is attended by leukopenia resulting from a decrease in both lymphocytes and neutrophils. After five days absolute lymphocytosis is manifest. The total leukocyte count is normal at the tenth day.

Necropsies of fetal and infantile victims of maternal infection have shown a variety of embryonal defects related to developmental arrest involving all three germ layers. Those defects most consistently associated with maternal rubella are microcephaly, cataract, patency of the ductus arteriosus and defects of the interventricular septum. Limited evidence suggests that agenesis of the organ of Corti underlies the deafness observed in affected infants.

**Symptoms** Fourteen to twenty-one days after exposure to the infection the onset of rubella is evidenced by symptoms variable

## A Guide to the Differential Diagnosis of Measles

++ present test available

+++ present and severe

cludes consideration of rubella scarlet fever exanthema subitum infectious mononucleosis secondary syphilis and drug eruptions. Of value in excluding these possibilities are the milder course and pinker rash of rubella the sore throat and leukocytosis of scarlet fever and serological tests for infectious mononucleosis and syphilis. The rash of exanthema subitum does not appear until the termination of fever. Fever enanthema and catarrh are uncommon with the cutaneous manifestations of drug hypersensitivity.

Specific laboratory diagnosis is still a research procedure (see Etiology).

**Prognosis.** Uncomplicated measles is rarely fatal and complete recovery from the disease is the rule. Fatalities are almost always the result of secondary streptococcal or pneumococcal pneumonia occurring principally in children below the age of five who become infected after the dissipation of passive neonatal immunity. Case fatality rates are also high in elderly and tuberculous patients. Cardiac decompensation is a common cause of death in patients over fifty years old.

The introduction of antimicrobial drugs effective against the usual secondary invaders has reduced the case fatality rate of measles sharply in recent years. The incidence of otitis media and pneumonia may be lowered by the prophylactic use of penicillin or a tetracycline early in illness.

Encephalitis occurs as frequently in mild as in severe measles. However modification of measles by gamma globulin prophylaxis (see below) affords an improved prognosis with reference to the encephalitic complication.

**Treatment.** There is no specific treatment for the fully developed disease. The administration of convalescent serum or gamma globulin during the period of incubation may prevent or modify the manifestations

of illness. The degree of modification obtained is dependent upon the quantity of antibody given and the time of its administration. In children of less than six years the intramuscular injection of 0.025 ml of gamma globulin per pound in the first half of the incubation period results in disease of lessened severity. Two to four times this amount will prevent disease in nearly 80 per cent of children. In older children and adults one and one half to two times as much globulin is recommended. In young or debilitated children the aim is complete prevention of disease. In children over five less subject to complications the goal of prophylaxis is attenuation of the infection sufficient to lessen symptomatology but not the development of effective immunity. However recent studies indicate that recurrences of measles may follow the gamma globulin modified disease in contrast to the solid permanent immunity conferred by the unaltered natural infection.

**Symptomatic Therapy.** In the absence of complications bed rest is the essence of treatment in this benign self limited disease. Codeine sulfate (0.015 to 0.06 gm) is useful in the amelioration of headache and myalgia and is effective in the management of cough. Acetylsalicylic acid (0.3 to 0.6 gm) may be employed for its analgesic and antipyretic actions. Diet should be unrestricted. Bright light is not an ocular hazard but photophobia may require darkening of the patient's room.

**Antimicrobial Prophylaxis.** The course of uncomplicated measles is not influenced by antimicrobial therapy. In common practice the incidence of serious bacterial infections is not sufficient to justify the routine prophylactic use of antimicrobials. Certain special circumstances may warrant full therapeutic dosage with penicillin or the tetracyclines in anticipation of the potentially fatal sequelae of pneumococcal or

gamma globulin have been equally disappointing prophylactic injection of susceptibles fails to protect them from the experimental disease. *Nevertheless women exposed to rubella in early pregnancy should receive the benefit of gamma globulin prophylaxis (as recommended for measles) despite its ambiguous status.* In natural epidemics an equivocally significant preventive effect has been noted.

Effective active immunization may be induced only by natural or experimental infection. The experimental infection is contagious (Krugman and others) and constitutes a potential hazard to pregnant women in the community. Deliberate exposure of prepubertal girls to the natural disease has been practiced and is a reasonable measure in view of the mildness of the disease.

## Cytomegalic Inclusion Disease

The term cytomegalic inclusion disease has been applied to a wide variety of infantile clinical syndromes associated with the finding of enlarged epithelial cells bearing intranuclear and cytoplasmic inclusions in salivary glands, liver, spleen, lungs and other viscera. Most cases are recognized only post mortem and thus comprise a pathological rather than a true clinical entity. Recently salivary gland virus has been recovered ante mortem from the viscera of infants in whom typical cytomegalic inclusions were also demonstrated. The fact that this virus induces similar inclusions in tissue culture and that it is neutralized by the serum of infected children suggests the probable relation of the salivary gland virus to cytomegalic inclusion disease. Limited studies with this newly recognized virus indicate that latent infection with the agent is widespread and that asymptomatic virus carriage and excretion may occur for many months in young children.

It is probable that a transplacentally acquired fulminant disease of the newborn associated with hepatosplenomegaly and hemorrhagic diathesis is a severe manifestation of cytomegalic inclusion disease. Primary pulmonary disease in the form of interstitial pneumonia is less certainly a form of the disease while an apparent association of the characteristic cellular inclusions with a variety of debilitating diseases may represent only a secondary reactivation by other processes of infection with salivary gland virus.

No specific treatment for the disease is known. Some patients with severe illness have survived. The demonstration in many adults of antibody to salivary gland virus suggests that cytomegalic inclusion disease may be benign in most cases.

No specific treatment for the disease is known. Some patients with severe illness have survived. The demonstration in many adults of antibody to salivary gland virus suggests that cytomegalic inclusion disease may be benign in most cases.

## Herpes Simplex

(*Herpes Febrilis*, *Fever Blisters*,  
Cold Sores)

**Definition.** Herpes simplex is an acute infectious disease of man characterized by the development in the skin or mucous membranes of groups of superficial vesicles containing clear fluid.

**Etiology.** Herpes simplex is caused by a virus. With the exception of herpes zoster all herpetic eruptions are thought to be induced by the same virus. This agent is of medium size and is 100 to 150 m $\mu$  in diameter. There are two types of herpetic disease: (a) primary infections in persons without antibodies and (b) recurrent attacks in persons with antibodies who are believed to be carriers of the virus. The virus is capable of infecting the central nervous system of various experimental animals and humans.

**Morbid Anatomy.** Hyperplasia of epithelial cells and necrosis and the development of vesicles containing clear fluid are the alterations usually seen in affected tissues.

in their occurrence and severity Cough sore throat and coryza may initiate the illness but are often absent headache malaise and myalgia may precede the eruption especially in young adults Commonly fever and obvious enlargement of posterior cervical nodes antedate the appearance of the rash Fever when present rarely exceeds 101 F and seldom persists beyond forty-eight hours Injection of the bulbar conjunctivae may be noted Palpable tender and occasionally visible lymphadenopathy involves postauricular and suboccipital nodes with sufficient frequency to be an important diagnostic sign Generalized peripheral lymphadenitis and more rarely splenomegaly may occur

The exanthema of rubella is usually apparent within twenty-four hours of the first symptoms as a faint macular erythema which first involves the face and neck Characterized by its brevity and evanescence it spreads rapidly to the trunk and extremities sometimes leaving one site even as it appears at the next The pink macules which constitute the rash blanch with pressure and rarely stain the skin Diffuse erythema on the second day of rash may closely simulate scarlet fever The eruption has vanished by the third day Rubella may occur without rash An exanthema has been described which is inconstant in form and occurrence and lacks the premonitory significance of the Koplik spots of measles The lesions consist of red macules which usually involve the soft palate

**Complications** Recovery is almost always prompt and uneventful although relapse occurs with greater frequency than with most viral diseases (5 to 10 per cent) Secondary bacterial infections rarely occur Rare complications are arthralgia neuritis gingivitis thrombocytopenic purpura and increased capillary fragility Heart block has been described A meningoencephalitis of short duration may occur one to six days after the appearance of rash Its incidence is estimated at 1 in 6000 cases and it is fatal in approximately 20 per cent of those afflicted

**Embryopathic Effects** The importance of rubella attaches to the well substantiated observation of Gregg that the occurrence of certain fetal abnormalities may be correlated with a history of maternal infection in the first trimester of pregnancy Infection of the mother may lead to intrauterine fetal death or stillbirth or more commonly to delivery of a viable infant of small size Such infants show retardation in mental and physical development and varying de-

grees of congenital abnormality The nature of the congenital defects observed has been related to the time of onset of the maternal infection and time of active proliferation of the primordia of organs subsequently manifesting defects Clinical manifestations in the infant may range in severity from dental hypoplasia to complete or partial blindness deafness and acyanotic cardiovascular disease Blindness is usually related to cataract deafness to the inner ear type and patent ductus arteriosus is the most frequently observed cardiovascular abnormality The latter condition has been related epidemiologically to the occurrence of rubella in contrast to other congenital cardiac defects

Original estimates of the incidence of congenital lesions following rubella were retrospective and therefore biased in the direction of finding a high rate of occurrence Recent prospective studies of pregnant women suffering rubella in the first trimester of pregnancy suggest that such women have a 90 per cent chance of giving birth to a normal baby

**Diagnosis** Rubella may be diagnosed with assurance only during an epidemic It may be difficult to distinguish from mild or modified measles infectious mononucleosis or scarlet fever Distinction from measles may be made on the basis of the pink nonstaining rash the milder course and the lesser catarrh of rubella Sore throat is a more prominent complaint in scarlet fever the course of infectious mononucleosis is often more protracted and splenomegaly is more frequent than in rubella Definitive diagnosis of scarlet fever and infectious mononucleosis may be made by laboratory means No specific laboratory test is available for the diagnosis of rubella

**Prognosis** Complete recovery from rubella is almost invariable The rare deaths attributable to rubella follow the infrequent complication of meningoencephalitis Infection in pregnancy constitutes a hazard to the fetus but not to the mother

**Treatment** There is no specific treatment for the disease Few patients suffer discomfort severe enough to warrant symptomatic medication Headache and myalgia may be controlled by acetylsalicylic acid bed rest is advisable for the duration of the fever

**Prevention** In contrast to measles current evidence is conflicting with regard to the prophylaxis of rubella with convalescent serum and gamma globulin Various lots of gamma globulin appear to vary in prophylactic potency some being completely ineffective Trials of convalescent serum

these tests antibody appeared in zoster and varicella convalescent serum to an almost identical degree and appeared to establish the identity of the viruses from each syndrome. The antibodies appear within four to seven days after onset and reach a peak in about three weeks with a subsequent slow decline. The agents cause focal cytopathic changes that are associated with intranuclear inclusion bodies in tissue cultures.

The portal of entry of the virus in zoster is unknown. It is not certain how it reaches the ganglia it affects. The occurrence of so-called symptomatic herpes zoster in association with various pathological processes about the ganglia, e.g. tuberculosis, syphilis or neoplasms suggests that the agent may either be present commonly in the environment or often latent in human tissues.

The portal of entry in varicella appears to be the upper respiratory tract. Varicella may be regarded as the early generalized infection with the virus and zoster is a late localized manifestation in the immune or partially immune person at a later age period.

**Morbid Anatomy** In zoster the basic lesion is in the dorsal root or extramedullary cranial nerve ganglia corresponding to the sensory innervation to the areas of herpetic eruption. The lesions consist of severe inflammation and destruction of ganglion cells and fibers.

The cutaneous vesicle of zoster and varicella is situated in the epithelial layer and there is marked inflammation of the corium. Acidophilic intranuclear inclusions are found in epithelial cells about the vesicle.

**Symptoms** In varicella the incubation period is usually fourteen to sixteen days although it may occasionally be as long as twenty-one days. Approximately twenty-four hours after the onset of fever crops of vesicles followed or accompanied by vesicles with surrounding erythema appear on the face and trunk spreading usually to the mouth, pharynx and extremities. In chickenpox the lesions are usually most abundant over the trunk while the face and extremities suffer the most damage from smallpox. Occasionally the generalized eruption will be accompanied by a localized eruption characteristic of zoster. The eruption occurs simultaneously with the fever and its duration is proportional to the height and persistence of the fever. Successive crops of lesions appear furnishing all of the characteristic stages of papules, vesicles and crusts at the same time over

the affected areas. There is general lymphadenopathy which is particularly noticeable in the suboccipital and the posterior cervical regions when vesicles occur in the scalp. The vesicles which are indistinguishable from those of zoster frequently become pustular and the crusts are often removed by scratching because of the itching. Impetigo, furuncles, septicemia and glomerulonephritis may complicate the picture. Vesicles on the laryngeal mucosa about the eyes and genitalia and in the hair present difficult problems. The encephalitis which occasionally complicates varicella is symptomatically similar to that accompanying zoster but is less common and less severe than that occurring in measles. Occasionally neuritis of the cranial nerves or myelitis may occur. Even temporary blindness may complicate the picture. Pneumonitis occurs in very severe or fatal cases particularly in adults and radiologically presents a characteristic bilateral nodular infiltration. A fatal nodular pneumonitis has been occurring more recently in persons who have contracted varicella while receiving steroid therapy which greatly diminishes resistance. Small depressed white scars on the skin may result from severe varicella and from scratching with secondary infection.

In cases of so-called idiopathic herpes zoster a typical attack rises without any obvious cause. There is a prodromal period usually of three or four days duration during which the patient feels ill, the temperature is elevated and there is more or less pain. At this time a definite diagnosis cannot be made but suddenly the erythematous and vesicular eruption appears with its characteristic distribution along the course of a sensory nerve usually of the trunk, occasionally in a trigeminal area. The eruption is frequently preceded or accompanied by enlargement of the regional lymph nodes. There is often an increase in the number of cells in the cerebrospinal fluid.

The febrile period lasts usually from three to five days and with its subsidence drying and healing of the cutaneous lesions take place. Secondary infection may delay healing and increase the tendency to scratch. Neuralgic pains may persist especially in elderly people and rarely there is some local residual paralysis.

Herpes zoster of the face occurs and is often severe. It usually results from involvement of the first branch of the sensory division of the trigeminal nerve and may lead to serious corneal ulceration which requires

Inflammation in the adjacent corium is associated with these changes. Infected cells often show nuclear inclusion bodies.

**Incidence.** Herpetic eruptions often develop without evident cause and in the absence of other pathological conditions. Frequently they occur during the course of various infectious diseases such as pneumonia, cerebrospinal meningitis, malaria, diphtheria, and so forth. In some persons recurrent herpes is seen, and in women it may be associated with menstruation. Injections of foreign proteins, vaccines, or fever therapy may precipitate an attack of herpes.

**Symptoms.** Primary infections common in young children are associated frequently with vesicular gingivostomatitis and may produce a constitutional reaction with fever, irritability, malaise, and local lymphadenopathy. The disease is self-limited, but symptoms may persist for seven to ten days.

Recurrent attacks common in adults usually are associated with herpetic eruptions which may occur anywhere in the skin or mucous membranes. Common sites are the lips, face, mouth, genitalia, conjunctiva, and cornea. The lesions at first cause small painful swellings that rapidly develop into vesicles surrounded by areas of erythema. The vesicles are usually filled with clear watery fluid, but suppuration may ensue. At times, particularly in the skin of the face, the distribution of lesions is similar to that seen in herpes zoster. Recurrent herpes simplex is usually a mild local lesion when it is not associated with another infectious disease; general symptoms are rarely encountered.

**Prognosis.** In the absence of secondary infection, the herpetic eruption gradually recedes and disappears. Corneal herpes may cause serious scarring and impairment of vision. One attack does not confer immunity against subsequent attacks.

**Treatment.** No specific treatment has been developed. Local applications may relieve pain and swelling, but do not shorten the course of the eruption.

## Varicella, Herpes Zoster

(Chickenpox, Zona  
Zoster, Shingles)

It has become apparent that these diseases may be considered as two syndromes resulting from the activity of a single virus of uniform antigenic composition without known strain differences. They thus may be described as two phases of a single disease.

**Definition.** *Varicella* is a mild communicable disease or syndrome confined chiefly to children. It is characterized by fever and an itching vesicular eruption of the skin and mucous membranes, individual lesions of which are surrounded by erythema. *Herpes zoster* is an acute infectious syndrome characterized by inflammation of one or more dorsal root ganglia or extramedullary cranial nerve ganglia. It is associated with a painful vesicular eruption in the skin or along the course of peripheral sensory nerves arising in the affected ganglia.

**History.** Barendsprung (1863) showed that zoster is associated with inflammation of the corresponding dorsal root ganglion. Head and Campbell (1900) made a classic study of the neuropathology. Bokay (1909) suggested that zoster and varicella are related etiologically. Kundratitz (1925) reported successful attempts to transmit zoster to human beings and also produced varicella by this means. Weller (1953) propagated the etiologic agent in cultures of human tissues.

**Etiology.** Present evidence strongly suggests that herpes zoster and varicella are caused by the same virus. The agent has been serially propagated *in vitro* in cultures of human tissue. Viral bodies from vesicles of varicella and zoster are brick shaped and identical in appearance and size (210 to 250 $\mu$ ). Vesicles twelve hours old contain numerous viral particles, but those twenty-four hours old yield very few. Roller tube cultures of virus from both varicella and zoster by Weller have permitted antigenic analyses by complement fixation, neutralization, and fluorescent antibody tests. In

rial from active lesions or variola crusts for transmission of the disease with a view to controlling it marks the first use historically of any active virus in planned transmission. The use of crusts or pustular lesions was later replaced by the use of fluid from early vesicles for scarification of human susceptibles. The resulting disease resembles varioloid (modified smallpox; see below) in that a local lesion occurs at the point of scarification followed in about eleven days by a mild generalized eruption which usually leaves no scars. Variola virus generally produces a mild disease similar to varioloid in anthropoids and in monkeys; it may occur by contact simultaneously with a human epidemic.

Transmission of smallpox to susceptibles may occur during all stages of the disease and until the scabs have disappeared. The disease apparently spreads principally by the airborne route. Dry desquamated crusts, dust and bedding of a patient's room as well as letters may remain infective for long periods and thus inhalation of the air from a patient's room may at times account for infection.

Occurrence of small outbreaks of smallpox even among the carefully vaccinated U.S. Army has demonstrated the need for vaccination in the presence of epidemics. For example, in 1945 and 1946 the U.S. Army in Korea suffered 121 cases of smallpox with 25 deaths. Revaccination of troops in this area with fresh vaccinia virus completely controlled the outbreaks, which however continued among the nonmilitary population.

The incidence of smallpox has been greater in the United States where vaccination is not nationally compulsory than in countries which require vaccination. In the United States the incidence is particularly high in those states which make little effort to vaccinate children against the disease but cases have been occurring in every state. In Philadelphia there were 2585 deaths from smallpox in 1872 and as late as 1904 over 200 deaths occurred yearly with the advent of compulsory vaccination; no deaths from smallpox have occurred since 1924.

Smallpox is more frequently fatal in infants and children. No transplacental immunity appears to be established—a situation similar to that of varicella. Smallpox contracted during pregnancy may involve the fetus and infants have been born suffering from a typical eruption. Pregnant women suffering from a severe attack of the disease usually abort. Men and women

are equally susceptible. Complete natural immunity is extremely rare but permanent immunity is generally established by a single attack, since there have been only a few reports of second attacks.

There appears to be a greater susceptibility among the colored races to the virus of smallpox. Although smallpox generally occurs during the winter months, this is probably due to closer contacts within closed spaces in the colder weather. Epidemics have been known to occur during the summer weather. There is a great variation in the severity of epidemics and fortunately those of recent years have been mild. This may be the result of greater emphasis upon cleanliness of the skin with resultant diminished danger of secondarily invading bacteria. The virus itself also appears to vary in virulence and many mild cases termed varioloid may occur. Such mild cases in the majority of instances appear to be a result of previous vaccination. On the other hand, the virus appears at times to gain in virulence as the epidemic progresses.

**Morbid Anatomy.** The pathological lesions are almost entirely in the skin and mucous membranes. The lack of a cornified epithelium in the mucous membrane prevents the development of a typical vesicle and pustule while ulcers with a deep crater and a surrounding red areola are common, similar to those of varicella but usually more extensive. These ulcers often occur in the buccal and nasopharyngeal mucosa, larynx, trachea, esophagus, vagina and even in the intestinal mucosa at times. The bladder, ureters and urethra are rarely involved. Secondarily invading streptococci and staphylococci frequently are present and increase the severity of the disease but the pustular stage of the eruption occurs irrespective of the presence or absence of these organisms. The local skin lesion is a multilocular pock in which the epithelium becomes degenerated and vacuolated with transudation of serum and the formation of a reticulum. As the reticular spaces swell with transudate and later with exudate their walls rupture to form the typical pustule. This pustule may be only in the epidermis but frequently extends into the corium. Such lesions contain both the typical cytoplasmic acidophilic inclusions lying close to the cell nucleus termed the Guarnieri bodies and also the intranuclear inclusions. A single cell apparently does not include both types of inclusions, i.e. both cytoplasmic and intranuclear. The round or oval Guarnieri body which is about 10

special care. The other cranial nerves are rarely affected.

**Diagnosis** In zoster because of the characteristic sensory nerve distribution of the vesicular eruption the diagnosis is usually not difficult after the lesions appear. In children and rarely in adults the local eruption may be followed by the appearance of numerous other vesicles apparently unrelated to cutaneous innervation.

Occasionally the virus of herpes simplex causes a vesicular eruption along the course of a cutaneous nerve usually limited in extent and it may involve the supraorbital branch of the ophthalmic nerve. This may closely simulate a mild herpes zoster. In such cases the presence of the virus of herpes simplex can be demonstrated in laboratory animals. The viruses of herpes zoster and of varicella on the other hand are transmissible only to man or cultures of human tissue. Immunological techniques have been developed for determining the presence of antibodies against the viruses. These may become useful in diagnosis. Varicella and zoster are frequently indistinguishable. The severe constitutional reaction caused by smallpox with a drop in fever as the rash appears together with uniformity of development of the eruption in all areas of the skin at the same time and the somewhat larger number of vesicles on the extremities as compared with the trunk serve to distinguish this disease from varicella. Also in smallpox the lesions tend to be deeper, shotty and umbilicated.

**Treatment** There is no specific treatment in zoster. Relief of pain and prevention of secondary infection of the surface lesions are the most important considerations. In mild cases salicylates or codeine is sufficient but in severe cases morphine or Demerol may be required to relieve pain. Locally antiseptic powders or ointments containing phenol, cocaine and the like may be used. Numerous special remedies have been offered, e.g. paraffin coating, ultra violet irradiation, x-ray therapy, certain antimicrobial drugs and so on but there is no convincing evidence that any of these procedures is of value. In so-called symptomatic herpes zoster treatment should be directed to the cause of the associated condition, i.e. syphilis, tuberculosis, tumor and so forth.

Postherpetic neuralgia may be prolonged and refractory to treatment. In patients who suffer intractable pain posterior root section or ganglionectomy may be necessary. For children with varicella, cutting and cleaning the fingernails are important.

## Smallpox

(Variola)

**Definition** Smallpox is an acute communicable disease characterized by severe constitutional symptoms and a single crop of skin lesions all proceeding at the same rate through a macular, papular, vesicular and pustular stage over a period of approximately three to ten days.

**History** In addition to certain evidence in the earliest records of China and Egypt suggesting its presence in both Asia and Africa, the disease undoubtedly changed the course of the Roman Empire and later altered the course of history among nations, kings and men of all nationalities throughout Europe and the British Isles up to the time of Jenner. In the Western Hemisphere the conquest of the natives by the European races may be attributed in no small degree to the devastating effect of the introduction of the virus of smallpox among the Indians by their conquerors. However, the discovery of vaccination by Jenner dramatically altered the role of the virus from that of the conqueror to that of the conquered.

**Etiology and Epidemiology** Smallpox is caused by a virus which in size and shape closely resembles the cuboidal or bricklike vaccinia virus. These viruses can readily be grown on the chorioallantois of the embryonated egg and have a diameter of about 200 m $\mu$ . They are readily stained by certain aniline dyes. The virus of smallpox is found in the vesicular fluid, being slightly larger than the varicella virus. It withstands drying for long periods without refrigeration which probably accounts for the ease with which it is transmitted. Both *in vitro* and *in vivo* tests have indicated the presence of common antigens and antibodies for both viruses.

**Variolation** the practice of using mate

in diameter with an appearance unlike any other exanthematous disease. Widespread tuberculids, all of the same size and symmetrically distributed, could have the same appearance. With the increasing size and tenderness of the papules, *multilocular vesicles* begin to form over the papules on about the sixth day, characteristically umbilicated because of a dry and depressed center. Some vesicles are superficial while others are deeper and not so readily recognized. By approximately the eighth day the vesicle becomes full of cloudy fluid and the typical *pustular rash* is in full bloom. The pustular nature of the lesion apparently is not dependent upon the presence of secondarily invading bacteria, although they are often present and greatly increase the danger of complications. The pustules are slightly larger than the papules, with somewhat greater elevation and have a characteristic greenish or grayish yellow color. A small red areola forms about each lesion at the time of vesiculation, a phenomenon which occurs synchronously with the development of an allergic response of the skin to variolous material.

Although the lesions may vary slightly in size, they proceed through each stage of development at the same time and do not appear in crops as is characteristic of varicella, with which otherwise mild smallpox might be readily confused. Although all the lesions appear at approximately the same time, a small percentage of them do not progress through all the characteristic steps but remain at times only as papules or with very slight evidence of vesiculation. In such lesions, involution occurs frequently in the earlier stage of the disease.

The rash usually appears on the face and about the wrists only slightly in advance of its appearance on the rest of the body and then rather rapidly involves the rest of the forearms, upper arms and thorax. The lateral region of the neck from the clavicle to the lower jaw, the inguinal areas and around the eyes usually have very few pocks. The abdomen and legs are often only slightly involved but in severe cases this may not be true. Such severe cases in which the rash is widespread and in which the lesions are so closely studded over the skin that they coalesce are termed *confluent*, whereas in the absence of coalescence the term *discrete* may be used.

Frequently these two forms, confluent and discrete, occur in the same patient; the confluent lesions appearing on the face and about the wrists while the discrete lesions appear on the thorax, abdomen and legs.

In certain confluent lesions the area involved has almost the appearance of a large abscess. On the face these lesions can be particularly distressing, often producing extreme discomfort. Edema may close the eyelids and involve the tissues of the neck as well. Edema of the hands and feet often occurs in children. At the height of the pustulation, lesions frequently occur in areas which must be watched closely for secondary infection: the mouth and nasopharynx, the prepuce, the labia and the vagina. Lesions on the palms and plantar surfaces are not apt to develop into vesicles and pustules but nevertheless form crusts. Marked pitting of the face or arms occurs as a rule only in the areas where the lesions are confluent.

The pustules and crusts itch severely and scratching must be prevented. Desquamation may begin at the twelfth to the fourteenth day. Unlike the branny desquamation of measles and scarlet fever, the desquamating crusts are thick and brownish yellow in appearance. A dark blue discoloration of the skin occurs in the area from which the crust has separated but this gradually and completely disappears.

**Blood.** There is usually a leukopenia together with a relative mononucleosis in the earlier stages of the disease but later a leukocytosis occurs, particularly during the pustular stage and when secondary complications occur. Anemia usually occurs together with enlargement of both the spleen and the liver. In the two hemorrhagic types of smallpox previously mentioned, considerable depression of the bone marrow and the liver may occur, resulting apparently in alterations in the platelets, fibrinogen and prothrombin. The exact origin of such hemorrhagic phenomena, however, is not entirely clear.

**Varioloid.** This term is usually applied to smallpox modified by a vaccination which has "taken successfully within approximately five years. The lesions are of the discrete type; the prodromal symptoms are rarely severe; there is no secondary rise of fever and the lesions frequently undergo involution with a markedly shortened course.

**Abortive Types.** Occasionally in recently vaccinated persons early involution of the eruption occurs even before vesicles are well established and in rare instances the eruption never develops a condition which is known as *variola sine eruptione*.

**Complications.** The common complications of smallpox may be considered as largely due to the secondary invasions of

FIG 1 Smallpox in a young man during the active stage of the disease. Note the even distribution of lesions on the face and trunk. (Courtesy of Drs. Vernon Knight and A. Ruiz Sanchez.)

microns in diameter with an unstained halo around it is probably a mass of variola virus imbedded in a matrix while the intranuclear inclusion apparently does not contain virus. The latter is also round or oval somewhat smaller than the Guarnieri body is acidophilic and is separated from the nuclear membrane in histological preparations by an unstained halo.

Two types of hemorrhage may occur with the lesions: (1) *purpura variolosa* or black smallpox in which extensive hemorrhages invade the corium only occurring however in the most severe cases soon after the onset of the disease and usually fatal and (2) *variola haemorrhagica pustulosa* in which small localized hemorrhages occur into the pock—a severe form of the disease but causing fewer fatalities than *purpura variolosa*.

Aside from the local changes in the cutaneous lesions of smallpox the general pathological picture as far as has been determined differs little from that resulting from other severely toxic states. The lungs are frequently involved by secondarily invading organisms such as pneumococci and streptococci resulting in bronchopneumonia which may be hemorrhagic at times. The liver is usually enlarged at the time the pustules develop and may also contain hemorrhagic foci. The spleen is similarly enlarged during the pustular stage and hemorrhages may also occur into the pulp. Because of the marked involvement of the skin of the face the cervical lymph nodes are also considerably enlarged chiefly with edema which extends beyond the capsule of the node. The marrow is notable for the

absence of polymorphonuclear elements and megakaryocytes and hemorrhages frequently occur in the more severe cases. Hemorrhages also may occur into the pelvis of the kidneys and into the ureters usually beneath the mucous membranes and severe degenerative changes in the kidneys themselves are often noted.

There is a characteristic proliferation in the hematopoietic system and extensive infiltration particularly in the liver, kidney, adrenals and testicle of mononuclear basophilic cells which in areas such as the testicle appear to cause pressure severe enough to produce occasionally localized necrosis.

**Symptoms. Clinical History.** The period of incubation lasts usually from ten to four teen days but may be somewhat shorter or longer. In vaccinated persons a longer incubation occurs at times followed by milder disease which has been termed *variola minor*. At onset the constitutional symptoms are severe with marked headache usually a chill or chilliness, aching of the back and limbs quite similar to that of epidemic influenza and a mounting fever which may reach a height of  $106^{\circ}$  or  $107^{\circ}$  F. In children convulsions and vomiting or drowsiness quickly followed by coma may occur. The patient is usually prostrated; the face is flushed, the pulse is usually full and bounding and marked restlessness which at times amounts to delirium supervenes.

Transient rashes resembling scarlet fever or measles may occur during the prodromal stages of the disease while the temperature is approaching or when it has reached its highest point. Such rashes occur only during the first two days and are found usually over the lower abdomen and the inner aspects of the thighs. The position of the rash and its lack of elevation serve to distinguish it from measles or scarlet fever. At times such a rash ushers in the more severe types of smallpox.

On the third or fourth day raised macules begin to appear over the face. The earlier these macules appear the more likely is the rash to become confluent. The macules rapidly develop into papules and with this development there is associated an immediate diminution in the severity of symptoms and the fever the patient becoming considerably more comfortable. Fever and symptoms usually increase later in respect to multiplication of staphylococci or streptococci in the pustules with their attendant complications. The single crop of papules are firm and shotty 2 to 4 mm.

in diameter with an appearance unlike any other exanthematous disease. Widespread tuberculids all of the same size and symmetrically distributed could have the same appearance. With the increasing size and tenderness of the papules, *multilocular vesicles* begin to form over the papules on about the sixth day characteristically umbilicated because of a dry and depressed center. Some vesicles are superficial while others are deeper and not so readily recognized. By approximately the eighth day the vesicle becomes full of cloudy fluid and the typical *pustular rash* is in full bloom. The pustular nature of the lesion apparently is not dependent upon the presence of secondarily invading bacteria although they are often present and greatly increase the danger of complications. The pustules are slightly larger than the papules with somewhat greater elevation and have a characteristic greenish or grayish yellow color. A small red areola forms about each lesion at the time of vesiculation a phenomenon which occurs synchronously with the development of an allergic response of the skin to variolous material.

Although the lesions may vary slightly in size they proceed through each stage of development at the same time and do not appear in crops as is characteristic of varicella with which otherwise mild smallpox might be readily confused. Although all the lesions appear at approximately the same time a small percentage of them do not progress through all the characteristic steps but remain at times only as papules or with very slight evidence of vesiculation. In such lesions involution occurs frequently in the earlier stage of the disease.

The rash usually appears on the face and about the wrists only slightly in advance of its appearance on the rest of the body and then rather rapidly involves the rest of the forearms, upper arms and thorax. The lateral region of the neck from the clavicle to the lower jaw, the inguinal areas and around the eyes usually have very few pocks. The abdomen and legs are often only slightly involved but in severe cases this may not be true. Such severe cases in which the rash is widespread and in which the lesions are so closely studded over the skin that they coalesce are termed *confluent* whereas in the absence of coalescence the term *discrete* may be used.

Frequently these two forms, confluent and discrete occur in the same patient; the confluent lesions appearing on the face and about the wrists while the discrete lesions appear on the thorax, abdomen and legs.

In certain confluent lesions the area involved has almost the appearance of a large abscess. On the face these lesions can be particularly distressing often producing extreme discomfort. edema may close the eyelids and involve the tissues of the neck as well. Edema of the hands and feet often occurs in children. At the height of the pustulation lesions frequently occur in areas which must be watched closely for secondary infection: the mouth and nasopharynx, the prepuce, the labia and the vagina. Lesions on the palms and plantar surfaces are not apt to develop into vesicles and pustules but nevertheless form crusts. Marked pitting of the face or arms occurs as a rule only in the areas where the lesions are confluent.

The pustules and crusts itch severely and scratching must be prevented. Desquamation may begin at the twelfth to the fourteenth day. Unlike the branny desquamation of measles and scarlet fever the desquamating crusts are thick and brownish yellow in appearance. A dark blue discoloration of the skin occurs in the area from which the crust has separated but this gradually and completely disappears.

**Blood.** There is usually a leukopenia to gether with a relative mononucleosis in the earlier stages of the disease but later a leukocytosis occurs particularly during the pustular stage and when secondary complications occur. Anemia usually occurs together with enlargement of both the spleen and the liver. In the two hemorrhagic types of smallpox previously mentioned considerable depression of the bone marrow and the liver may occur resulting apparently in alterations in the platelets, fibrinogen and prothrombin. The exact origin of such hemorrhagic phenomena however is not entirely clear.

**Varioloid.** This term is usually applied to smallpox modified by a vaccination which has taken successfully within approximately five years. The lesions are of the discrete type; the prodromal symptoms are rarely severe; there is no secondary rise of fever and the lesions frequently undergo involution with a markedly shortened course.

**Abortive Types.** Occasionally in recently vaccinated persons early involution of the eruption occurs even before vesicles are well established and in rare instances the eruption never develops a condition which is known as *variola sine eruptione*.

**Complications.** The common complications of smallpox may be considered as largely due to the secondary invasions of

FIG 4 Same patient as in Figure 3 during convalescence after treatment with intravenous injections of oxytetracycline (Terramycin) for secondary invaders

staphylococci and streptococci. Abscesses septicemia nephritis erysipelas laryngitis and the various lower respiratory infections can usually be traced to these organisms together with at times pneumococci. Corneal ulcers and pustules of the eyelids are not uncommon. Rarer though still important complications are diarrhea and otitis media in children and in adults hemiplegia encephalitis polyneuritis decubitus ulcers and gangrene.

**Diagnosis** Difficulties in diagnosis arise chiefly from the following conditions:

**Variceloid** with the involution of many of the lesions can be confused at times with varicella. In such cases one must depend upon the appearance of varicella in crops of lesions in all stages of development and also upon the difference in distribution of varicella which is more plentiful on the trunk.

The severe hemorrhagic forms can be confused with septicemia or severe meningococcal infection. Blood cultures should establish the diagnosis.

The initial rash which occurs in severe forms may be confused with that of measles or scarlet fever. The short duration of the early evanescent rash of smallpox, its distribution in the diaper area and the other accompanying symptoms should assist in differentiation.

**Pustular syphilis** are at times extremely difficult to differentiate from smallpox. In certain instances one can depend only upon the history and serological tests for syphilis for differentiation.

The isolation of the virus on the chorioallantois of the embryonated egg has been

FIG 5 Smallpox in an unvaccinated child showing distribution of eruption

quite successful inasmuch as pocks are produced by variola or vaccinia while material from lesions of varicella does not produce pocks. Since differentiation from varicella presents clinical difficulties at times such isolation may be important. The best method of diagnosis however is in the microscopic study of smears from the smallpox lesions in which the elementary bodies are readily distinguished.

**Prognosis** The prognosis in smallpox depends largely upon the severity of the particular case. In the epidemics of recent years the mortality has been distinctly lower than in the prevaccination era. The

FIG 6 Same patient as in Figure 5 showing eruption on back and palms

FIG 7 Typical temperature curve from a case of smallpox illustrating the secondary rise

cases accompanied by high fever are more likely to be fatal. Complications particularly those in the respiratory tract add to the seriousness of the prognosis. The mortality rate is greatest under five and over forty-five years of age.

**Treatment** The principal consideration in the treatment of smallpox is the prevention of secondary infection of the vesicles and pustules. The secondary elevation of temperature which usually follows the appearance of the vesicles and pustules may depend partially upon the bacterial invasion of the lesions particularly by staphylococci and streptococci. Treatment therefore should be aimed essentially as in varicella toward the prevention of itching and the cleansing of fingers, the skin and garments or clothing which may come in contact with the lesions. Also scrupulous care must be taken of the eyes, nose and mouth in the more severe cases. The advent of the sulfonamide drugs and penicillin has assisted greatly in the control of secondary infection of the lesions of smallpox. Swabbing the lesions in wet dressings of potassium permanganate 1:4000 may prevent serious infection. It is important that crusts should not be removed too quickly in view of the possible resultant scarring. Bathing the lesions gently with hot water or antipruritic lotions should be done to alleviate the itching.

Dehydration is a frequent severe complication of smallpox and should be avoided.

by rectal intravenous or hypodermic fluids particularly glucose if vomiting occurs. The possible benefit of convalescent serum has not yet been determined. The isolation period should be at least fourteen days and longer if the lesions remain in an active stage.

**Prophylaxis** The problem of vaccination is considered properly in the article on Vaccinia. Emphasis must be placed upon the fact that vaccination even during the incubation period of the disease may prevent its development. Strict quarantine is essential.

The disease is air borne as well as transmitted by contact or by direct droplet hits from the patient; nasopharyngeal secretions means of sterilization of the air must be considered as well as the prevention of close contacts and of spread by fomites.

## Vaccinia

Vaccination or active immunization against smallpox by means of the virus of cowpox is the first procedure of this type known to medicine. This discovery and development by Jenner long before bacteria or viruses had been identified is one of the most dramatic events of medical history. The antigenic relationship of the vaccinia virus to cowpox and smallpox viruses is not clearly understood since in certain areas of the world the vaccinia virus appears to have derived from cowpox virus and in other areas from smallpox virus. Whatever the derivation of the vaccinia virus apparently it has become antigenically stable and produces a characteristic pox lesion. In view of the proved immunity produced by vaccination with vaccinia virus against smallpox these two viruses antigenically must be quite similar.

**Etiology and Epidemiology.** Vaccinia or cowpox virus has been studied as diligently and has received as adequate definition as any virus. According to the definition of some workers it is cuboidal and according to others bricklike with a shape and size similar to those of the smallpox virus. In purified preparations of the virus obtained from infected epidermal cells of a rabbit it has been determined by a variety of calculations that a single infective particle apparently will produce the lesion of vaccinia.

When variolation is performed five days after vaccination only a local lesion results while at eleven days variolation produces no lesion. Vaccination takes during the prodromes of smallpox but not when performed a few days after the eruption has appeared. Serums obtained from cases of either vaccinia or variola neutralize both viruses.

Malnutrition in rabbits has been shown to reduce the size of the vaccinal lesion. Also methionine, choline and estrogenic substances have reduced the susceptibility of rabbits to vaccinia. The available antimicrobial drugs have shown relatively slight inhibiting effects on the vaccinia virus. Storage with glycerol at 5 to 10° C and lyophilization have been adequate to maintain viral activity. Ultraviolet light and x-ray radiation inactivate the virus.

The virus of vaccinia obtained from the contents of vesicles of vaccinated calves ordinarily has been preserved by dilution 1:5 in 50 per cent glycerin saline solution containing 1 per cent phenol. As distributed in capillary glass tubes in the United States

the presence of fewer than 50 nonpathogenic bacteria per dose is required by law. At a temperature below 5° C the virus can be kept active for at least three months but it is readily inactivated at room temperature. More recently it has been grown in tissue cultures by the methods of Rivers and Goodpasture which have almost entirely eliminated bacterial contamination. These preparations can be used intradermally and produce a much milder reaction with a closed lesion. Although the protection afforded against smallpox is probably as solid as that produced by the more usual material sufficient experience with its value in the face of an epidemic of smallpox has not been obtained to warrant its widespread use.

**Proper Age for Vaccination.** In view of the fact that severe reactions particularly the complication of encephalomyelitis are less apt to occur when vaccination is performed during the first year it is best to vaccinate an infant about the fourth to the sixth month. The choice of months however should vary according to a number of factors. It is essential that no fixed or invariable order of immunization procedures be followed in infants since epidemics of communicable diseases, respiratory infections, the convenience of the family and the physician, the weather and other factors should all be considered in such procedures. It is wise to avoid hot weather because of the possibility of a marked febrile reaction and to avoid vaccination within a certain period following illness and until the latter half of the first year in premature infants or those who have suffered from nutritional difficulties. The presence of such cutaneous conditions as eczema, impetigo and other skin diseases in the infant or in close contacts of the infant should cause postponement of vaccination until the skin is normal. In chronic eczema or in other cutaneous conditions which are not readily curable, however, tissue culture virus injected by the intradermal method can often be used successfully with less danger of bacterial contamination.

**Choice of Site for Vaccination.** The area of choice for both sexes is the skin on the posterior and upper portion of the arm close to the axilla where the scar is not readily visible and where the friction is minimal.

**Method of Vaccination.** In the development of techniques for vaccination over many years the objective has been to produce a lesion which results in as inconspicuous a scar as possible but still

produces an optimal degree of immunity. Although serological means of determining such immunity are not available, experience in the presence of epidemics of small pox and with the results of revaccinations has indicated that the take from the recent methods of vaccination resulting in a small scar may not be as highly protective as the "take" with the large scar or scars resulting from the older methods of vaccination. Many physicians believe that scarification or drilling of a large area of skin and the resultant lesion are essential for a solid and more lasting immunity. The danger of secondary infections from the larger lesions and the added discomfort and fever do not justify such a procedure except in the presence of epidemic or endemic smallpox when two to four separate areas of skin should be inoculated.

The methods recommended at present are of three types: (1) single scratch or incision method; (2) drill method; (3) multiple pressure method. In these methods the objective is to permit the virus to enter the skin in as small an area as possible without sufficient trauma to draw blood. The skin of the selected site should be cleansed thoroughly with sterile cotton and ethyl alcohol, acetone or ether care being taken to avoid abrasions which might result in multiple "takes." The site should also be permitted to dry thoroughly after cleansing in order to avoid inactivation of the virus. The vaccine tube should remain in the refrigerator until immediately before use when the ends may be filed and broken off and the small rubber bulb attached for expressing the fluid.

**1 Scratch or Incision Method.** A single scratch  $\frac{1}{4}$  to  $\frac{1}{2}$  inch in length should be made in the skin with a sterile needle or point drawn through the drop of lymph. More than one scratch may be made if the first appears to be insufficient, but cross scratches should never be used. The needle or point should then be placed horizontal with the skin and rubbed gently over the scratched area after which the drop of lymph should be rubbed off lightly with dry sterile cotton.

**2 Drill Method.** Multiple pricks are made through the drop of lymph with the needle held vertical to the skin surface. The number of pricks should be limited to five or six and the lymph may then be wiped off with dry sterile cotton.

**3 Multiple Pressure Method.** The needle or point is held at an angle of approximately 45 degrees with the skin surface and is moved up and down rapidly with pres-

sure on the skin sufficient to puncture it lightly six to ten times. Erythema but no blood or serum should be noted after the procedure and the lymph may be wiped away immediately with sterile cotton as in the other methods. In the youngest infants a greater number of punctures is advisable.

In all these methods no dressing should be used but scrubbing the area with soap and water should probably be avoided for the following twenty-four hours.

**Types of Reaction.** In general it may be said that the longer the incubation period the greater is the susceptibility of the vaccinated person and the more severe is the reaction. The small-sized reaction which occurs within the first twenty-four to seventy-two hours and disappears rather rapidly denotes a high degree of immunity whereas the usual "take" with the large reaction which begins to develop typical signs after five or six days and reaches its height at eight or nine days is evidence of a highly susceptible person. Between these extremes of reaction and susceptibility there are many intermediate responses and degrees of immunity which follow a characteristic pattern.

In order of degree of immunity which they indicate the following reactions can be classified approximately as follows:

**1 Immediate or Immune Reaction.** This occurs as a papule with a light surrounding erythema usually reaching its height during the first three days after the inoculation and then receding rapidly in size and reactivity. Persons showing this type of reaction often have been previously vaccinated within a relatively short time.

Inactive virus as well as active virus can give an immune reaction although the former cannot produce immunity. Thus unless vaccination is performed with the same material on a number of persons, some of whom would have primary "takes" or accelerated (vaccinoid) reactions, one may be mistaken concerning the immunizing value of the vaccine material used.

**2 Accelerated Reaction.** In such persons the immunity is less than in the preceding type; the reaction reaches its height in from three to five days and there is a vesicle rather than a papule with a marked erythema extending well out from the base of the vesicle. The entire area rarely extends over  $\frac{1}{2}$  to  $\frac{3}{4}$  inch in diameter. Slight fever, malaise, chilliness, aching, local tenderness and slight enlargement of the draining lymph nodes frequently occur. By some this type of reaction has been termed *vaccinoid*.

**3 Primary Vaccination Reaction or Typical Take** In the typical take little is noted at the site of inoculation except for a punctate area of erythema until the fifth day when a vesicle appears with a rapidly increasing erythema and induration about it. Usually the vesicle erythema and induration increase up to the ninth day when the total area involved ranges approximately from the diameter of a silver half dollar up to the diameter of a grapefruit or even at times beyond in adults. The vesicle itself if the vaccination is properly performed rarely exceeds  $\frac{1}{4}$  to  $\frac{1}{2}$  inch in diameter but the area of erythema and induration may not only extend in a wide circular areola but may reach out toward the draining lymph nodes to involve areas of skin many inches from the central vesicle. In certain instances where primary takes have occurred by mistake on the tips of the fingers acute lymphangitis resembling that due to hemolytic streptococci may occur during the height of the reaction and extend well up the arm—apparently the result of the tension produced in such a restricted area. In the larger reactions the draining lymph nodes are swollen and tender. Fever is usually present in infants at times reaching 104 or 105 F and remaining at that elevation for several days. Extreme discomfort with chills aching and localized tenderness is common. Also in such reactions small additional vesicles may occur about the periphery of the indurated area. As a result of the irritation and itching infants will frequently scratch the vesicle and inoculate themselves else where on the body at the site of open skin lesions or scratch marks. As the reaction subsides the vesicle which is typically umbilicated becomes darker in color with a deeper central crater and gradually changes into a hard black crust which falls off in several weeks. The remaining scar is bluish red at first and in time becomes a firm white area characteristically round and irregularly pocked.

Failure to react in one of these manners is not an indication of immunity as is often incorrectly supposed but rather an evidence in almost all instances of an inactive virus vaccine. In certain cases the lymph may have been washed off with soap and water or possibly methyl alcohol or some other improper antiseptic may have been used for preparation of the site of inoculation but it is probable that in only rare instances does the child fail to react when the virus is active and applied properly on a dry site. Occasionally hypersensitivity re-

actions in the form of urticarial or maculopapular rashes appear seven to eleven days after vaccination. When bullae occur the mucous membranes may be involved. Such an erythema multiforme plurifocialis may be quite serious.

**Care of Reaction** Of primary importance in the care of the lesion resulting from the typical take is maintenance of dryness and a free flow of air about the vesicle. For this reason shields should never be used. In addition a relatively sterile surface may be maintained on the vesicle and on the entire area about the reaction by sponging them gently with alcohol and cotton at least twice daily being careful to leave the surface of the vesicle intact. If a serous discharge occurs from the vesicle because of excessive tension or more commonly trauma alcohol and cotton should be used three to four times daily and a loose piece of gauze attached to the clothing over the vesicle or attached to the skin by adhesive tape placed well outside the indurated area. If a discharge sufficient to cause crusting occurs so that the gauze becomes attached to the vesicle an antibiotic ointment may be applied to the vesicle at least twice daily following the usual cleansing with alcohol and a piece of gauze may be added for further protection for the clothing.

**Frequency of Vaccination** Opinions vary as to the required frequency of revaccination but in general five to seven years may be considered a proper interval between vaccinations with the additional provision that vaccination be performed whenever epidemics of smallpox are impending.

**Complications and Sequelae** The most dangerous complication of vaccination is that of pyogenic infection resulting from neglect dirt scratching and other skin infections. Such infection is usually of staphylococcal origin with cellulitis but hemolytic streptococci may at times be responsible and septicemia erysipelas or scarlet fever may also be seen. Such infections increase the size and severity of the reaction considerably and result finally in a large and disfiguring scar.

**Vaccinia gangrenosa** or prolonged generalized vaccinia an almost invariably fatal but rather rare complication occurs as a slowly spreading gangrenous vaccinal involvement of the skin surrounding the take with serpiginous ulceration edema with gangrene and satellite takes which are incorporated into the slowly spreading swollen and gangrenous slough. This is associated with extreme toxicity fever and incapacity of the skin to localize the infec-

tion Many of these patients have agamma globulinemia

Hyperimmune human gamma globulin developed by Kempe and given parenterally in 10 ml amounts every one or two weeks for four to six weeks has been of curative value

The additional necrosis caused by pyogenic complications is an excellent medium for the growth of tetanus bacilli Tetanus occurs less frequently now than formerly but is still an important consideration where dirt and squalor prevail Under such conditions the use of tetanus toxoid for immunization should precede vaccination against smallpox The elimination of shields in the care of the usual "take" has also eliminated much of the danger of tetanus

Scratching may cause secondary vesicles at distant points particularly about the genitalia and face where severe scarring can occur A generalized vaccinia is seen at times in an infant with eczema or some other generalized skin disease when it has been exposed to another vaccinated member of the household If an eczematous child requires vaccination the hyperimmune gamma globulin should be injected in a single dose of 0.6 ml per kg of body weight for prevention of eczema vaccinatum The same dosage may be used for

an eczematous contact or for treatment of a generalized vaccinia Umbilicated lesions may extend over most of the body with high fever and extreme toxicity In such cases lesions of the eye should be handled most carefully because of the danger of corneal perforation At times generalized urticaria roseola or purpura is seen when the reaction is at its height Occasionally viremia results in viral osteomyelitis with afebrile but extensive multiple bony necrosis and eventual slow healing Pyogenic osteomyelitis is rare

Postvaccinal encephalitis has rarely been reported in the United States but has been recorded more often in England and Europe It usually appears about ten days to two weeks after the height of the vaccination reaction although it may be seen earlier or later The severity of this complication appears to be entirely unrelated to the severity of the "take" or to the batch of vaccine used The onset is generally abrupt with high fever disorientation and at times with coma or convulsions A stiff neck positive kernig sign increase or absence of reflexes and positive Babinski sign are usually present Weakness and paralysis of the extraocular muscles are common as well as paralyzes of the face pharynx and limbs As a rule the cells are increased

FIG 8 Hyperallergy expressed as roseola vaccinosa Note the marked area of the vaccination lesion on the arm

in the cerebrospinal fluid chiefly the lymphocytes although at first there may be an increase in polymorphonuclear cells. The sugar and chloride of the cerebrospinal fluid ordinarily are not greatly altered but the protein is usually increased as is also the pressure. The course of the disease is usually extremely stormy with either a rapid progression to death or an equally rapid improvement. The case mortality of this complication ranges from 30 to 50 per cent and even though rapid improvement occurs residual mental retardation or spasticity may remain. There is no specific therapy available other than lumbar punctures for relief of cerebrospinal fluid pressure and the proper orthopedic care of any paralyzed or spastic skeletal muscles. It is of particular importance that this complication is almost never seen in infants less than one year of age and is practically unknown in the first months of life. This constitutes a strong argument for early vaccination against smallpox.

## Mumps

### (Epidemic Parotitis)

**Definition.** Mumps is an acute communicable disease caused by a virus. It usually manifests itself by involvement of the salivary glands but frequently involves other tissues, notably those of the testes and the central nervous system.

**History.** The clinical and epidemiological features of mumps were well described long before the etiology was known. Advances in knowledge have been rapid since 1934 when Johnson and Goodpasture isolated the virus by inoculating saliva of patients into the parotid duct of monkeys. Enders and associates developed a complement fixation test which made possible a definite diagnosis and was useful in epidemiological and immunological studies. A notable advance was made by Habel who succeeded in growing the virus in chick embryos. Levins and Enders then adapted the virus to the allantoic sac and demonstrated its hemagglutinating properties. These developments facilitated studies on prophylaxis and immunization which have been carried on by Henle and associates. Habel and others. Infection of volunteers by Marx provided data on the frequency of subclinical infection and the period of communicability. Kilham showed that the virus was pathogenic for suckling hamsters and mice.

**Etiology.** Mumps virus is of medium size with a diameter calculated by various observers to be between 90 and 135  $\mu$ . It is readily isolated from the saliva of patients with parotitis and from the cerebrospinal fluid of patients with meningo-encephalitis. In monkeys it causes parotitis. In suckling mice or hamsters it may cause fatal meningo-encephalitis. It grows readily but slowly in the yolk sac or amniotic sac of chick embryos and can be adapted to the allantoic sac. After multiple chick embryo passages the virus may become less virulent for man. Erythrocytes of chickens and humans are agglutinated by virus suspensions.

**Morbid Anatomy.** Observations of infected parotid tissue from humans are few. In general the changes observed resemble those noted in infected monkeys. Sero-fibrinous exudate in the interstitial tissue, vascular engorgement and lymphocytic infiltration of the tubules are noted. Necrotic glandular cells and polymorphonuclear cells are found within the lumina. Biopsy specimens from the testis show marked edema, perivascular lymphocytic infiltration, focal hemorrhages, pronounced destruction of germinal epithelium and plugging of the tubules by epithelial debris, fibrin and polymorphonuclear cells. In most instances the lesions are focal and some areas escape

**Pathological Physiology** The serum amylase of most patients is elevated during the first few days of illness apparently because of the acute inflammatory process in the parotid glands rather than an accompanying pancreatitis.

**Incubation Period** The incubation period is most frequently between seventeen and twenty-one days. Extremes of from eight to thirty-five days have been reported.

**Communicability** The virus has been repeatedly recovered from the saliva during the three days following onset and on one occasion as late as the sixth day after onset. Experimental studies show that it may be present for several days before the onset of symptoms and may also be recovered from persons with inapparent infections. It is presumed to enter the host by the oral or respiratory route through the medium of infected droplet or direct contact. Spread to other tissues probably takes place by way of the blood stream. The degree of communicability of mumps is relatively low. Many persons reaching adult life are susceptible to infection.

**Age Incidence** The disease is most frequent between the ages of five and fifteen. All ages may be affected. High attack rates have been noted in all age groups in isolated populations such as the inhabitants of Pacific islands.

**Immunity** Immunity is generally of long duration. Second or even more rarely third attacks have been reported but are exceedingly uncommon. There is no convincing evidence that the patient with unilateral parotitis is any more likely to experience a second attack than one with a bilateral parotitis. The development of immunity as a result of inapparent infection is a common occurrence.

**Clinical Manifestations** *Parotitis* Before the appearance of parotid swelling there may be a prodrome of one or two days duration during which the patient experiences feverishness, chilliness, malaise, anorexia and headache. In mild cases this is not observed. Swelling of one or both parotid glands then occurs. In the latter event the two glands may be affected at the same time or in sequence. The swelling is accompanied by variable amounts of pain about the angle of the jaw and by difficulty in moving the jaw.

The swelling in the parotid region fills the area behind below and anterior to the angle of the jaw extending up to the zygomatic arch. The lobe of the ear is pushed out and upward. The affected glands feel firm and are moderately or extremely

tender. The orifice of Stenson's duct may appear reddened. The temperature is usually between 100° and 103° F but may rise to higher levels. By the second or third day the swelling has usually reached its maximum and begins to subside. The time required for swelling to disappear completely is subject to considerable variation. As a rule this occurs within a week but swelling may persist for considerably longer periods.

Accompanying the parotitis or rather infrequently in the absence of obvious parotitis swelling of the submaxillary or sublingual glands may occur. This is more readily determined by palpation than by inspection. Edema of tissues surrounding affected glands is commonly observed and may involve much of the anterior surface of the neck and the area lying over the anterior surface of the manubrium sterni.

**Orchitis** Orchitis is an infrequent manifestation of mumps before puberty but is common in adults. The overall incidence has been estimated as approximately 20 per cent. Considerable variation in incidence has been reported in different epidemics. A small proportion of patients may have orchitis without evidence of parotitis.

In general orchitis develops as the parotitis is beginning to subside. Pain and swelling of the affected testis are noted and the temperature rises accompanied by chilliness and malaise. The affected testis may enlarge to two or three times its normal size and is painful and exquisitely tender. Epididymitis, hydrocele and scrotal edema may be present. Usually only one gonad is involved but both may be affected. The swelling and constitutional symptoms progress for two or three days and then subside over a period of a week or more. In certain instances fever drops precipitously rather than by lysis. A considerable amount of atrophy as determined by palpation occurs in approximately one half of the patients but sterility seldom ensues. This may be explained by the fact that even when there is extensive involvement of both testes the distribution of the inflammatory reaction is spotty and certain seminiferous tubules are spared. Psychological rather than organic factors are presumably responsible for the occasional development of impotence following an attack of mumps orchitis.

**Meningoencephalitis** Wide variations in the incidence of meningoencephalitis in different epidemics have been reported. In certain series in which the cerebrospinal fluid has been examined routinely pleocytosis

tosis has been found in as many as one half and signs of meningo-encephalitis in more than one fourth of the patients. Though signs of central nervous system involvement commonly follow the development of parotitis they may be observed before or simultaneously with the parotid involvement. Furthermore it is important to stress the fact that meningo-encephalitis may occur in the absence of any salivary gland involvement.

The temperature is usually markedly elevated in the presence of meningo-encephalitis and the patient complains of severe headache, photophobia, neck stiffness, nausea and vomiting. Delirium may occur but in most instances the sensorium remains clear. On physical examination the patient is often drowsy but can be roused; the neck and back are stiff and Kernig's sign is present. Lumbar puncture shows an increased cerebrospinal fluid pressure, an increase in cell count and a slight increase in protein. The cells are predominantly lymphocytes and the cell count though variable tends to be higher than in certain other neurotropic viral diseases. The prognosis is favorable. There is reason to believe that death when it occurs results from a chain of events initiated by the mumps infection rather than from a direct effect of the virus. Convalescence may be slow but sequelae are uncommon.

**Other Manifestations.** Pancreatitis is suggested by the appearance of epigastric pain, nausea and vomiting. There may be tenderness on deep palpation and occasionally the pancreas is palpable. Determination of the serum amylase is of no value in this situation, however, for elevated serum amylase values occur commonly in apparently uncomplicated mumps. Oophoritis is probably not uncommon but the diagnosis is difficult to establish with certainty. It should be considered when a patient complains of lower quadrant or low back pain and when a tender enlarged ovary is felt. Other less common manifestations of mumps include mastitis in either sex, involvement of lacrimal glands, thyroiditis, deafness, seventh nerve paralysis and optic neuritis. Myocarditis has also been described. Polyneuritis and myelitis occur but can hardly be considered to be due to a specific effect of the mumps virus since they have been observed in a wide variety of infectious diseases.

**Diagnosis.** The clinical diagnosis in a patient with parotitis who has been exposed to mumps is seldom difficult. Occasionally cervical lymphadenitis, parotitis of bacterial

etiology and salivary calculi must be considered. The diagnosis may be more difficult when only submaxillary or sublingual glands are involved. Meningo-encephalitis without accompanying parotitis must be differentiated from other neurotropic viral diseases in particular nonparalytic poliomyelitis. A history of exposure to mumps is often an important clue. When the issue is in doubt it can now be resolved by serological tests.

Complement fixation, agglutination inhibition and neutralization tests have been developed for the diagnosis of mumps. In all tests two serum specimens should be tested for definitive diagnosis rests on the demonstration of a significant increase in antibody titer. The first specimen should be taken as early as possible and the second between ten and twenty-one days after onset.

The total leukocyte count may be low, normal or slightly elevated. A considerable proportion of patients show a lymphocytosis. Because this is not uniform the blood picture is not of great value in diagnosis.

**Prognosis.** The outlook is almost invariably favorable. A fatal outcome is stated to occur less than once in a thousand cases.

**Treatment.** Patients should be kept at rest in bed. Pain associated with parotitis can usually be relieved by salicylates supplemented if necessary by codeine. Application of heat or cold may afford comfort. In orchitis Demerol (0.05 to 0.1 gm) or morphine (0.01 to 0.015 gm) may be necessary. The testes are more comfortable when supported. Cortisone (0.1 to 0.3 mg per day) may relieve the pain and tenderness of mumps orchitis but does not prevent the manifestation of the infection. The effect of cortisone on the sequel of testicular atrophy is not known.

Convalescent serum and pooled gamma globulin have been recommended for alleviating the severity of the illness and preventing the development of orchitis. Stilbestrol has been widely used in treating orchitis. Evidence for the effectiveness of all these substances is conflicting. There is limited but more convincing evidence that globulin prepared from serum which contains mumps antibody in high titer may reduce the incidence of orchitis.

**Prevention.** Tests to Determine Susceptibility. Intradermal tests and measurement of serum antibodies have been used to determine susceptibility in exposed persons. Both procedures may provide useful information but neither is infallible.

**Passive Immunization.** Gamma globulin

from normal serum or preferably from serum known to contain mumps antibody in high titer may prevent the development of mumps when given within a week of exposure. Convalescent serum may also be effective but carries the risk of viral hepatitis even when irradiated. Passive immunity is of short duration and the patient remains susceptible to infection later in life when complications are more likely to occur.

**Active Immunization** Some reduction in the incidence of mumps has been shown among persons vaccinated with either inactivated virus preparations or with live virus attenuated by chick embryo passage. The degree of protection obtained has fallen somewhat short of expectations.

## Psittacosis

(Ornithosis)

**Definition** Psittacosis (ornithosis) is a specific infectious disease endemic among various members of the bird kingdom. The infectious agent is transmissible to man in whom it usually induces an atypical form of pneumonia. In a strict sense the term *psittacosis* designates the disease in birds of the order *Psittaciformes* (parrots, parakeets and the like) and the disease communicated by them to man. The discovery that birds belonging to other orders may be infected similarly and may transmit the infection to man led to the suggestion (Meyer) that all instances of the disease, whether avian or human, be included under the broader term *ornithosis*.

**History** Psittacosis in man was a rarely recognized disease until 1929. The disease was described by Jurgensen 1876 and by Ritter 1880 who noted the association between it and the presence of ill birds. Morange 1895 gave the disease its name. The etiological agent was discovered by Bedson, Western and Simpson 1930 who showed it to be filterable and present in infected tissues of parrots and human beings. Levinthal and Coles as well as Lillie 1930 independently described "elementary bodies" in infectious material. Krumwiede, McGrath and Oldenbusch 1930 demonstrated the susceptibility of mice to infection with psittacosis virus. Rivers and Berry 1930, 1932 induced psittacosis pneumonia in monkeys. Coles 1940 showed that pigeons were infected with the virus and Meyer, Eddie and Yanamura 1942 demonstrated that these birds could cause infections in man.

**Etiology** The etiological agent is included among the viruses of the psittacosis lymphogranuloma group. The agent of psittacosis, one of the largest of known viruses, has not been shown to be capable of multiplication in the absence of living cells. Elementary bodies are readily demonstrable in infected tissues of birds, mammals and human beings; many investigators consider them to represent the virus.

A number of different strains of the virus are recognized. Infected birds represent the source of infection in the majority of human cases. In man the disease appears to be more severe when acquired from members of the parrot family but pigeons have been responsible for numerous infections in human beings and some cases have been attributed to contact with infected canaries, finches, petrels or chickens. Infected birds may or may not appear ill. The virus is present in the nasal discharges and droppings of most infected birds and contaminates their feathers and cages. It is relatively stable, withstands prolonged drying and enters man via the upper respiratory tract. Both sexes and persons of all ages are susceptible, although children appear to be more resistant than adults. The virus is present in the sputum of patients and direct transmission from man to man occurs, although it is not common. The disease usually occurs in a sporadic manner or affects small groups of persons exposed to a common avian source of infection.

**Morbid Anatomy** Infection by viruses of the psittacosis lymphogranuloma group induces a variety of pathological alterations. Among infected birds the lungs are seldom altered. The chief abnormalities are seen in the liver and spleen, which are enlarged and show areas of focal necrosis.

In man the chief abnormalities are seen in the lungs. The pneumonic lesions are

usually patchy and irregularly distributed. They develop near the hilum and spread toward the pleura which is only rarely involved. There is cellular infiltration of the alveolar walls and spaces. Lymphocytes and other mononuclear cells predominate.

**Pathological Physiology and Chemistry** The leukocyte count is usually within normal limits although transient leukocytosis or leukopenia may occur and a relative monocytosis may develop. Albuminuria is seldom marked and may be absent. The erythrocyte sedimentation rate is increased. Cyanosis is seldom a striking feature probably because the alveolar spaces in the pneumonic lesions are usually not completely filled with exudate.

**Symptoms** The incubation period ranges from seven to fifteen days. The symptoms vary widely as does the severity of the disease. The source of the virus appears to be of some importance. Infections derived from birds of the parrot family are often more severe than those contracted from pigeons. The onset may be abrupt or insidious. The initial symptoms are malaise, anorexia, fever, headache and backache. Chills may occur. The cough is usually nonproductive and may be severe and paroxysmal. The temperature rises fairly rapidly, is usually remittent and may remain elevated for two or three weeks after which it falls by lysis. The pulse rate is usually slow in relation to the temperature. The respiratory rate is often normal or only slightly increased. Pleural pain is rarely present. In severe cases a high temperature, restlessness, insomnia and delirium may develop. Headache, cough and constipation with abdominal distention may be prominent features. Marked increase in both the pulse and respiratory rates may occur and indicates a poor prognosis.

Pulmonary consolidation develops in the great majority of patients but may be difficult to detect by physical examination particularly during the first week of illness. Usually it begins at the hilum and spreads outward. Despite the absence or paucity of physical signs of consolidation, roentgenograms of the chest usually show evidence of pneumonia early in the course of the disease. The roentgenogram reveals hazy, patchy, irregularly distributed areas of increased density which are seldom lobar in distribution. Pleural fluid rarely is evident and when present is small in amount. Diarrhea, epistaxis and even scattered macules resembling rose spots may occur. Some patients produce large amounts of sputum which may be slightly blood

streaked but is not rusty. Extension and spread of the pneumonic process occurs frequently and migratory pneumonia has been observed. Relapses occur occasionally. Complications are not frequent but phlebitis may develop. Convalescence is slow and after a severe attack may be prolonged.

**Diagnosis** The development of symptoms and signs indicative of an atypical form of pneumonia in a person who has recently had contact with birds should suggest the possibility of psittacosis. A normal respiratory rate, a relatively slow pulse rate, a normal leukocyte count, the absence of classic physical signs of pneumonia and the presence of consolidation on the roentgenogram are characteristic but not pathognomonic. Without the assistance of laboratory tests the disease rarely can be distinguished from atypical pneumonias of other etiology. Mild cases may be confused with pulmonary tuberculosis or sporadic influenza. Severe cases may resemble typhoid fever. In appropriately equipped laboratories experienced personnel may be able to recover psittacosis virus from the sputum and thereby establish the diagnosis. The complement fixation reaction with serum and psittacosis antigen is an important diagnostic aid.

**Prognosis** The prognosis is influenced by the source of the virus, the age of the patient, the extent of pneumonia and prompt use of effective chemotherapy. Infections derived from birds of the parrot family are most severe. Infections contracted from other members of the bird kingdom appear to be less severe.

**Treatment** Psittacosis in man could be eradicated if exposure to infected birds could be eliminated. Birds belonging to the parrot family and pigeons appear to constitute the chief sources of human infections. Patients with the disease may transmit it to those who care for them. The virus is present in the sputum and may be disseminated by coughing.

Psittacosis is one of the very few viral diseases for which specific treatment is available. Chemotherapy with certain antimicrobial drugs is effective in the disease. In man sulfonamides are not of much value nor is streptomycin. Penicillin in doses of 300,000 to 600,000 units per day may in some cases be helpful. The tetracyclines are the drugs of choice and appear to be more effective than chloramphenicol. Doses of 1 gm of a tetracycline drug by mouth every six to eight hours during the first two days and every twelve hours thereafter should be given for one week. Sympto

matic and supportive therapeutic measures should also be used

## Lymphogranuloma Venereum

(Lymphopathia Venerea Climatic Bubo)

**Definition** Lymphogranuloma venereum is an infectious disease systemic in nature and varied in manifestations which produces specific involvement with acute and chronic inflammation of the lymph channels and nodes of the genitals and rectum. The disease is transmitted by sexual contact. Early manifestations include an evanescent genital lesion followed by subacute regional lymphadenitis progressing to suppuration and sinus formation. General dissemination of the infective agent constitutional symptoms and rarely involvements of distant structures occur. Later progressive inflammatory disease of the local lymphatics and surrounding tissues leads to lymphedema, ulceration and disfigurement of the genitals and to proctitis, perianal fistulas and rectal stricture.

**Etiology** The causative agents of lymphogranuloma and psittacosis and of certain diseases of birds and animals are known as the psittacosis lymphogranuloma group and are tentatively classified intermediate between the viruses and rickettsiae. Common characteristics of the psittacosis lymphogranuloma group include large particle size, antigenic interrelationships and susceptibility to certain antimicrobial agents. The lymphogranuloma microorganism is pathogenic for the chick embryo and produces meningoencephalitis on intra-cerebral inoculation into mice.

**Epidemiology** Although lymphogranuloma venereum was long considered a disease of warm climates, there is ample evidence of its world wide distribution. As with other

venereal diseases, the prevalence of the infection is determined by the promiscuity of the population and is greatest in young adults. Surveys based on intradermal reactions to killed lymphogranuloma agent suggest that inapparent infection and latent disease are frequent in promiscuous persons. Existence of the carrier state has been shown by isolation of the agent from the genitals or rectum of asymptomatic persons of both sexes (Coutts). Accidental infections of laboratory personnel have been described.

**Pathogenesis** After a variable incubation period of from three to twenty days, an initial lesion (vesicular, papular or ulcerative) may occur at the site of infection. More commonly, the first evidence of the disease is involvement of the inguinal lymph nodes beginning two weeks to three months after exposure. The primary lesion having been unnoticed or absent.

The inguinal adenitis, unilateral or bilateral, is a subacute diffuse process affecting the entire chain of lymph nodes and often the femoral group as well, producing the "sign of the groove." Characteristic of the inflammatory reaction is the formation of multiple small abscesses within the nodal parenchyma, subsequently spreading to the surrounding pericapsular tissues and to the overlying skin. The tissues become indurated, matted and fused; the skin reddened and brawny. Pain and tenderness are variable. Ultimately, rupture of abscesses through the skin results in chronically draining sinuses.

Systemic invasion by the lymphogranuloma agent may be manifested by fever

FIG 9 Lymphogranuloma venereum unilateral involvement five days after appearance of inguinal adenitis. (Courtesy of Howard and Strauss. *New England Journal of Medicine*.)

arthralgias or arthritis various types of cutaneous eruptions and by ocular lesions in the form of conjunctivitis or iritis. The nervous system may also be involved as evidenced by headache meningeal signs and abnormalities in the cellular and protein content of the cerebrospinal fluid. The agent has been isolated both from locally involved sites and from blood and cerebrospinal fluid.

In females the less frequent occurrence of early external manifestations is presumably related to the lymphatic drainage of the site of entry of the agent. On this basis primary infection of the vulva or introitus results in inguinal involvement inoculation through mucous membranes of the upper vagina or cervix leads to inflammation of perirectal and pelvic lymphatics. The latter type which in its early stages may simulate gonococcal disease has serious long term implications in the form of proctitis and rectal stricture.

Late manifestations of lymphogranuloma venereum include disfiguring lesions of the external genitals (elephantiasis or in females esthiomene) and the anorectal syndrome. In the former persistence of the infectious process in the skin subcutaneous tissues and lymphatics of the genitals produces brawny induration and slowly developing enlargement of affected soft tissues over periods of months or years. Finally suppuration fistula formation and scarring lead to disfigurement and to functional impairment. The anorectal syndrome is initiated early in the disease by proctitis with tenesmus and a bloody or purulent discharge. Later chronic cicatrizing inflammation of the rectum and perirectal tissues leads to obstipation and to diminished caliber of the stools. At the onset of rectal stricture edema is a contributing factor and at this stage the process is amenable to medical treatment. The late fibrous stricture however may require colostomy. In addition there may be involvement of the rectovaginal septum progressing to fistula formation. Perianal fistulas also occur and because of lymphatic obstruction dilated perianal lymph channels (lymphorrhoids) resembling hemorrhoids develop. It is to be emphasized that lymphogranuloma is the commonest cause of benign rectal stricture.

**Diagnosis.** Isolation and identification of the infective agent of lymphogranuloma are experimental rather than practical procedures. Consequently the diagnosis must usually be based on clinical grounds combined with indirect laboratory evidence and the exclusion of other diseases. Prior to the

appearance of the lymphadenitis the primary lesion of lymphogranuloma may simulate herpes progenitalis. Both early syphilis and chancroid mimic early lymphogranuloma. Tuberculosis and lymphoma frequently require diagnostic consideration as may tularemia and plague under appropriate circumstances. Clinical similarities as well as terminology cause confusion between lymphogranuloma venereum and granuloma inguinale a separate disease caused by the Donovan body. Late anorectal lymphogranuloma must be differentiated principally from ulcerative colitis and cancer.

To ensure the absence of early syphilis darkfield examinations of material expressed from genital lesions or aspirated from enlarged inguinal nodes should be performed as well as follow up serological observations. It should be pointed out that false positive serological tests for syphilis occur in about 20 per cent of patients with lymphogranuloma. The clinical manifestations of chancroid and lymphogranuloma may be indistinguishable.

The *intradermal test* introduced by Frei now employs as antigen killed lymphogranuloma agent harvested from yolk sacs of chick embryos (Lygranum). Sensitivity develops in ten to thirty days after onset of the disease and persists for years in the absence of treatment. Thus a positive reaction is indicative of either present or past infection. The sensitivity of the test is high 90 per cent or more of patients with lymphogranuloma giving positive results. Positive reactions are not induced by use of the test material itself but reactivation of latent lymphogranuloma has been described following this procedure. Cross reactions with diseases due to other agents of this group may occur.

The *complement fixation test* uses an antigen similar to the skin testing material. As with the intradermal test a positive complement fixation reaction (except as noted subsequently) indicates present or previous infection. In Heyman's study all of twenty seven patients with early lymphogranuloma proved by isolation of the agent had complemented fixation titers of 1/40 or more and most had titers of 1/160 or higher. However more important than titer was the serological trend determined by study of acute phase and convalescent serums collected over periods of weeks frozen and tested simultaneously. "Cross reactions" may occur in infections due to other agents of the lymphogranuloma psittacosis group. Ordinarily these do not constitute a prob-

lem because of differing clinical manifestations as well as because of the lower titer of most cross reacting serums. In psittacosis however high titered complement fixation reactions with lymphogranuloma antigen may occur.

**Hyperglobulinemia** Hyperglobulinemia with elevated total serum proteins and reversal of the albumin globulin ratio is common. Although the increase in globulin may develop within a few days after the appearance of buboes several weeks or more may be required. In addition administration of effective antimicrobial agents may prevent or reverse hyperglobulinemia.

As chancroid may simulate lymphogranuloma with respect to both primary lesion and bubo diagnostic tests for both diseases should be carried out concurrently. For chancroid smears and cultures employing appropriate techniques and an intradermal test using killed Ducrey bacilli as antigen have demonstrated value. Inasmuch as the histopathology of each of these two venereal infections is distinctive and frequently diagnostic biopsy may prove helpful. Biopsy is usually necessary for the diagnosis of either tuberculous lymphadenitis or lymphoma.

**Prognosis** Early lymphogranuloma has a variable and unpredictable course. Prompt diagnosis and adequate treatment to terminate infectiousness and to prevent late complications are important. The longer the duration the slower and less complete is the therapeutic response. The end stages of late lymphogranuloma fibrous strictures and scars are usually resistant to medical treatment.

It has been suggested that there is an increased occurrence of genital and anal cancer in patients with symptomatic late lymphogranuloma. In view of this possibility biopsy should be freely utilized in patients with known or suspected lymphogranuloma.

**Treatment** Although penicillin has been demonstrated to be active against experimental lymphogranuloma infections it has not proved effective clinically in the dosages employed. Both the sulfonamides and the tetracyclines are somewhat effective but the therapeutic response to either may be incomplete. In the treatment of early lymphogranuloma with sulfonamides 3 or 4 gm should be administered daily for three to six weeks depending on clinical response. For disease of long duration treatment may be initiated as above then the dosage decreased to 2 gm daily for a prolonged period (several months). With tetra-

cycline compounds 500 mg four times daily is recommended. The individual dose may be reduced later to 250 mg and continued three to six weeks for early infections and for more prolonged periods for late lymphogranuloma. Combined sulfonamide and tetracycline therapy may prove more effective than either alone.

Fluctuant buboes respond to repeated aspirations incision and drainage or the excision of involved structures is unnecessary and may be harmful. With respect to rectal stricture digital dilatation should accompany administration of antimicrobial agents and combined treatment should be continued for several months if possible before resorting to surgical procedures. Plastic operations on the genitals should likewise be deferred until the effects of antimicrobial therapy have been observed. In spite of long standing disease surprising recovery of form and function may occur. Conversely treatment may not be wholly effective even in early lymphogranuloma.

## Foot and Mouth Disease

(*Aphthous Fever*)

Foot and mouth disease is a viral infection of animals chiefly cattle which occurs in man only with great rarity. Infection when it does occur in man presumably results from direct contact with the virus either in the laboratory or from handling the tissues or body fluids of infected animals. The disease in man is characterized by a short incubation period followed by

the appearance of a febrile illness with vesicular lesions of palms soles and the oropharyngeal mucosa. Neurological involvement has not been reported and the disease is self limited. There is no treatment of established value. The tetracycline drugs have yielded inconclusive results in the treatment of animals. Prevention of the disease in man has not been extensively studied for man generally has a high degree of resistance to the infection. An effective vaccine for use in cattle has been developed.

## Lymphocytic Choriomeningitis

**Definition.** Lymphocytic choriomeningitis is an acute disease of man characterized by a grippelike illness followed in certain instances by an acute aseptic meningitis.

**Etiology.** The causative agent is a filterable virus of medium size pathogenic for guinea pigs hamsters and monkeys by various routes of inoculation and for rats and mice by the intracerebral route. It produces inapparent infection with subsequent development of antibodies in dogs pigs and rabbits. The virus belongs to the viscerotropic group producing an interstitial type of pneumonia areas of round cell infiltration particularly in the liver and choriomeningitis. During infection a soluble antigen is produced to which complement fixing antibodies develop in convalescence. Neutralizing antibodies to the virus itself are distinct and do not appear until several months after infection.

**Incidence.** The disease occurs sporadically. Cases have been recognized in various parts of the United States the British Isles Europe and Asia. It usually occurs in fall winter or spring.

**Epidemiology.** The virus is harbored by mice in which latent infection passes from one generation to the next. Cases have been traced to direct or indirect contact with these rodents. Dogs develop inapparent infection with this virus and the ability of certain blood sucking insects to transmit the disease has been demonstrated so that

other possible sources of human infection exist. Among laboratory animals this infection is a frequent cause of difficulty because of its communicability and it has been contracted by a number of laboratory workers. Transmission of infection from one human being to another has not been observed.

**Pathology.** Few proved fatal cases have been studied. The principal findings have been interstitial bronchopneumonia and lymphocytic infiltration of the choroid plexus and meninges in the acute phases. The meningeal inflammation subsides slowly and may occasionally be followed by thickening infiltration and scarring of the ventricular walls and subarachnoid space.

**Symptoms.** The incubation period is short. Within a few days after exposure fever develops. This is usually irregular and may be accompanied by chills and symptoms of "the grippe" malaise headache generalized aches and pains and anorexia. Pharyngitis cough and signs of pneumonia may occur. During this phase which lasts from a few days to two weeks there is leukopenia. In some patients complete recovery ensues in others approximately fifteen to twenty days after exposure and often after a remission of a day or two the temperature again rises and evidence of meningitis appears: headache drowsiness nausea vomiting nuchal rigidity Kernig's sign bradycardia and changes in the deep tendon reflexes. During this phase the leukocyte count is usually normal and lumbar puncture yields fluid under increased pressure with elevated protein normal concentration of glucose and from 50 to 2500 cells per cu mm almost all lymphocytes. The meningeal phase lasts about a week with gradual subsidence of fever and symptoms but considerably slower disappearance of the changes in the cerebrospinal fluid. Cases exhibiting only the systemic symptoms of the prodromal phase have been diagnosed rarely but probably occur as often as cases of meningitis. The majority of proved cases have had the syndrome of aseptic meningitis (see section on Non-purulent Meningitis). Several patients have been observed in whom the stage of invasion of the central nervous system was characterized by encephalomyelitic symptoms with both motor and sensory disturbances. Rare fatal cases with encephalitis or with pharyngitis pneumonitis high fever prostration and leukopenia which gradually changed to a leukocytosis have been described.

FIG 10 Course and laboratory findings in a patient with proved lymphocytic choriomeningitis probably acquired from handling a recently trapped mouse since the virus of this disease was subsequently obtained from mice trapped in the home (Reprinted from *Medicine* Vol 21 with permission of the publishers Williams and Wilkins)

**Diagnosis** The syndrome of acute aseptic meningitis" originally described by Wallgren is relatively common. Only a few instances are actually due to the virus of lymphocytic choriomeningitis. The latter should be considered when there has been an exposure to mice, other animals capable of harboring the virus, or blood sucking insects, and in patients who have had a prodromal illness of several days duration with a latent period before the development of meningitis. The diagnosis is proved on isolation of the virus by inoculation of guinea pigs with blood taken during the prodromal phase or with cerebrospinal fluid obtained during the meningeal phase. In intracerebral inoculation of white mice with infectious material gives rise to characteristic convulsions and death in six to ten days. Serologic diagnosis depends upon demonstration of the development of complement fixing antibodies for the soluble antigen (four to six weeks after onset) and of neutralizing antibodies for the virus which appear later (two to three months after onset).

A common cause of acute aseptic meningitis is mumps. It occurs in infectious mononucleosis and in infections due to many viruses capable of invading the central nervous system. In any case of a lymphocytic reaction in the cerebrospinal fluid, the possibility of parameningeal infection, brain abscess, torulosis, tuberculosis,

leptospirosis and syphilis should be excluded.

**Prognosis** Most patients recover completely. Death due to overwhelming infection and sequelae due to fibrosis and scarring of the choroid plexus or meninges have been observed occasionally.

**Treatment** Treatment is purely symptomatic.

**Prevention** Control of rodents and vermin in the home and in places where laboratory animals are kept should reduce the incidence of the disease. Persons trapping mice should handle animals and traps with care.

## Rabies

### (Hydrophobia Lyssa)

**Definition** Rabies is an acute infectious disease of the central nervous system to which all warm blooded animals and man are susceptible. The virus frequently present in the saliva of an infected host is usually transmitted by bites or licks. The disease characterized by a profound dysfunction of the central nervous system ends almost invariably in death.

**History** Rabies was probably the disease to which Homer referred in the Iliad when he wrote *κυα λυσσην ηρα*. Democritus and Aristotle recognized it as a disease of animals and Celsus described its transmissibility to man. Rabies as a disease of wild animals had been known in Europe as early as the thirteenth century and in the eighteenth century epizootics among domestic animals were recorded in urban centers. It was first reported in the Americas in 1709 by Fray José Gil Ramirez in Mexico and was described in the Virginia Colony in 1753. Since that time its presence has been evident throughout the North and South American continents.

The transmission of rabies from the saliva of a rabid dog to a normal dog was first recounted by Zinke in 1809 and in 1879 Galtier described the susceptibility of rabbits to rabies and their use for diagnostic purposes. The modern concept of the disease was developed by Pasteur and his associates (1881). They not only identified the causative agent but also were able to modify its pathogenicity by serial intracerebral passages in laboratory animals (1884).

**Etiology, Host Range and Experimental Infection** Virus recovered in nature the so called *street virus* is characterized by extremely variable usually long incubation periods and by its ability to invade salivary glands as well as central nervous tissue. The term *fixed virus* is used for strains of rabies which have been adapted to laboratory animals by means of serial intracerebral passages. Fixed virus is characterized by a short incubation period (usually four to six days) and by its apparent inability to multiply in salivary glands. Prolonged cultivation of some strains of rabies virus in the developing chick embryo has resulted in modification to the point of complete loss of pathogenicity for animals injected extra neurally.

In discussing the properties of the virus both the type of virus and the source of infected material have to be considered. In general it may be said that the virus having a diameter of 100 to 150 mμ can be filtered through bacteria retaining porcelain filters. It is filterable but not readily through Seitz EK filter pads. Rabies virus

is speedily inactivated by sunlight ultra violet irradiation formalin bichloride of mercury and strong acids. It is relatively resistant to ether and chloroform and quite resistant to phenol. In aqueous solution its thermal death point is reached at 56° C after an exposure of one hour. It survives desiccation from the frozen state and may be best preserved in dry form.

The host range of rabies is one of the widest in the disease spectrum. All mammals including bats are susceptible. The virus is also pathogenic for birds but to a lesser degree than for mammals. The disease is not transmissible by insects or arthropods. The virus cannot invade the body through intact skin and is apparently harmless when ingested. However infection through unabraded mucosa seems possible.

Rabbits guinea pigs Swiss albino mice and hamsters are most commonly employed for experimental infection. Hamsters are remarkably susceptible to intramuscular infection with street virus but intracerebral injection of albino mice is usually employed for diagnostic purposes.

**Epidemiology and Epizootology** Johnson distinguishes two epidemiological patterns of the disease the natural sylvatic type maintained in wildlife and the urban type which occurs in domestic dogs. The sylvatic type is present in enzootic form in many areas of the world in such wild animals as wolves (Arctic regions of Canada Eastern Europe Turkey Iran) mongooses (South Africa the Caribbean) bats (Central and South America and the United States) foxes coyotes skunks (United States). In the urban type a number of domestic animals including cows and cats may become involved but the propagation of the virus in dogs is solely responsible for the epizootics after the elimination of canine rabies there is no evidence that rabies persists in urban areas.

Epizootics of rabies can occur in any climate during any season of the year. Wars and mass movements of men and animals favor the geographical spread of the disease. Man becomes an accidental host upon exposure to the infected saliva of the biting animal and although wild animals are often sources of human rabies dogs are mostly responsible for human infection. The attack rate in man following exposure depends to a certain extent on the location and severity of the inflicted wounds. Head and neck bites lead to a higher incidence of infection than bites on other parts of the body. Although the bites of rabid wolves

are apparently very dangerous an attack rate of 47 per cent was recently observed in 32 persons bitten by the same animal

**Morbid Anatomy** At autopsy the brain is friable edematous and congested the convolutions are broad and flattened Marked vascular congestion of the white and gray matter may extend to the medulla and the spinal cord Virus infected salivary glands are usually soft and swollen On microscopic examination of the central nervous system the nonspecific findings consist of hyperemia perivascular and perineuronal infiltration with mononuclear cells and marked neuronal degeneration Mononuclear cell infiltration of periacinar interstitial tissue accompanied by degeneration of acinar cells may be observed in the parotid sublingual and submaxillary salivary glands

If proper staining technique is applied intracytoplasmic inclusion bodies can be demonstrated in the neurons of the majority of rabies cases These so called Negri bodies are pathognomonic for rabies encephalitis In their absence the lesions cannot be distinguished from those observed in other viral encephalitudes

**Incubation** The incubation period varies from ten days to over twelve months As minor and seemingly insignificant contacts with rabies virus in the saliva of an animal not obviously sick at the time of exposure are sometimes forgotten claims of extended incubation periods (one to two years) have to be critically evaluated In dogs signs of rabies may appear after an incubation period of ten days to several months In one instance rabies developed in a dog eight and one half months after artificial exposure by intramuscular inoculation with street virus

The length of the incubation period is related to the amount of virus introduced at the time of exposure and to the severity of the laceration The site of the original exposure does not seem to affect the duration of the incubation period

**Clinical Manifestations** Dogs In dogs the prodromal phase of the disease consists of fever failure to eat hyperesthesia and very frequently change in the tone of the bark However these signs are often so slight that only a trained observer may note them Altered disposition of the animal is also characteristic The prodromal period may last from a few hours to several days and gives way to the excitation phase in which the animal grows unnaturally restless and agitated General tremor due to stimulation

of the muscular system is frequent In the furious type of the disease agitation intensifies as the illness progresses The animal erratic and aggressive growls and barks constantly It will grab viciously at any object or animal encountered At this stage an unrestrained animal sometimes leaves home and travels great distances inflicting damage on other animals and humans along the way Convulsive seizures are often observed and the animal may become completely paralyzed In many cases however the excitation phase predominates until the time of death

In the paralytic type of rabies the excitation phase may be slight or totally absent and the disease is characterized only by the paralytic syndrome Paralysis of the lower jaw accompanied by excessive salivation appears as an early symptom and the animal acts as though choking on a foreign body Paralysis of the muscles of phonation may lead to loss of the bark As the disease progresses paralysis of the posterior extremities sets in followed by general paralysis and death The time from the onset of the disease to the death of the animal ranges from one to eleven days On the other hand dogs may die suddenly without noticeable signs of illness

**Man** In man the prodromal phase is marked by fever malaise nausea and sore throat Abnormal sensations around the site of infection such as intermittent pain tingling or burning are of diagnostic significance Extreme stimulation of the general sensory system is manifested by hyperesthesia of the skin to temperature changes and to drafts and by acute sensitiveness to sound and light Increased muscular tonus prompt gag and corneal reflexes dilation of pupils and increased salivation may be present

As the disease progresses spasmodic contractions of the muscles of the mouth pharynx and larynx on drinking—and later at the mere sight of fluid—are observed in the majority of cases This dysfunction of deglutition lent the disease its common name *hydrophobia* or fear of water Spasms of respiratory muscles and convulsive seizures leading to opisthotonos may occur The pulse is very rapid Periods of irrational and often maniacal behavior are interspersed with those of alertness and responsiveness Paralysis of the muscles of phonation may lead to hoarseness or loss of voice

The excitation phase may remain predominant until the time of death However in many cases it gives way shortly before

## Indications for Specific Post Exposure Treatment\*

NATURE OF EXPOSURE	CONDITION OF ANIMAL		RECOMMENDED TREATMENT
	At time of exposure	During observation period of 10 days	
I No lesions Indirect contact only	Rabid	—	None†
II Licks			
1 Unabraded skin	Rabid	—	None‡
2 Abraded skin scratches and abraded or unabraded mucosa	(a) Healthy	Healthy	None
	(b) Healthy	Clinical signs of rabies or proved rabid	Start vaccine at first signs of rabies in animal
	(c) Signs suggestive of rabies	Healthy	Start vaccine immediately Stop treatment if animal is normal on fifth day after exposure
	(d) Rabid escaped killed or unknown	—	Start vaccine immediately
III Bites			
1 Simple exposure	(a) Healthy	Healthy	None
	(b) Healthy	Clinical signs of rabies or proved rabid	Start vaccine at first signs of rabies in animal
	(c) Signs suggestive of rabies	Healthy	Start vaccine immediately Stop treatment if animal is normal on fifth day after exposure†
	(d) Rabid escaped killed or unknown or any bite by wolf jackal fox bat or other wild animal	—	Start vaccine immediately
2 Severe exposure (multiple or face head or neck bites)	(a) Healthy	Healthy	Hyperimmune serum immediately No vaccine as long as animal remains normal
	(b) Healthy	Clinical signs of rabies or proved rabid	As in III 2 (a) but start vaccine at first sign of rabies
	(c) Signs suggestive of rabies	Healthy	Hyperimmune serum immediately followed by vaccine Vaccine may be stopped if animal is normal on fifth day after exposure
	(d) Rabid escaped killed or unknown Any bite by wild animal or bat	—	Hyperimmune serum immediately followed by vaccine

Hyperimmune serum to be effective must be given within 72 hours of exposure

These indications apply equally well whether or not the biting animal has been previously vaccinated

\* Prepared by Expert Committee on Rabies of World Health Organization

† Start vaccine immediately in young children and patients where a reliable history cannot be obtained

‡ Alternative treatment would be to give hyperimmune serum and not start vaccine as long as animal remained normal

death to cessation of muscle spasms hyporeflexia or areflexia and to general paralysis of the flaccid type

In some cases particularly those in Trinidad resulting from vampire bat infection the excitation phase is almost totally absent and the disease is characterized by ascending paralysis without hydrophobia. Without an adequate history of exposure this type is indistinguishable from other viral encephalides and the diagnosis may be overlooked.

**Diagnosis** Profound dysfunction of the central nervous system accompanied by impairment in deglutition following a history of exposure to a bite or lick of an animal facilitates the clinical diagnosis. Isolation of virus from saliva obtained in the course of the disease and from brain tissue obtained at autopsy followed by proper identification of the agent by means of neutralization test will confirm the diagnosis. Syrian hamsters rabbits guinea pigs and mice are used for diagnostic purposes. The presence

of Negri bodies is pathognomonic but their absence does not exclude the diagnosis of rabies encephalitis since isolation of the virus may still be accomplished

**Prognosis** Although inapparent infection with street virus may be induced artificially in laboratory animals and although animals have recovered completely after exhibiting signs of the disease there is no proof in stance of the recovery of man from rabies

**Treatment Prevention** A treatment for rabies does not exist in the strict sense of the word for there are no therapeutic measures available which would save the life of a person exhibiting symptoms of the disease A protective type of treatment can be used following exposure to the virus and prior to the development of the disease Particularly in a rabies endemic area and adjacent territory this protective treatment has to be based on the assumption that every animal inflicting a wound on a human may be rabid until proved otherwise by clinical observation or by failure to discover the virus in its tissues after death

**Local Treatment of Wounds** All bite wounds including skin abrasions exposed to licks of animals should be treated immediately by thorough cleansing with soap or detergent solutions This does not preclude the use of strong mineral acids such as nitric acid which may be particularly useful in the treatment of deep puncture wounds where other methods of cleansing are not very effective In laboratory animals a cationic detergent Zephiran chloride applied in a 1 per cent solution to wounds artificially contaminated with the virus has been found to be effective in preventing rabies In another series infiltration of the wound with antirabies serum together with thorough cleansing and application of nitric acid where the site permitted gave excellent results

The local or parenteral application of an antimicrobial drug is of no value as a prophylactic measure except in combating concomitant bacterial infections

**Indications for Specific Treatment** These are summarized in a table prepared by the Expert Committee on Rabies of the World Health Organization Emphasis is placed on the condition of the biting animal at the time of the exposure and during the ensuing ten days It is assumed that the saliva of an animal which is not obviously ill at the time of exposure may be infectious during a maximum period of five days pre

ceding the appearance of clinical signs of disease

**Passive immunization** against rabies by the administration of hyperimmune anti serum is introduced as a standard procedure in view of the overwhelming experimental evidence obtained in favor of such treatment Because of the existence of various vaccine preparations no emphasis is placed on the use of any special type of vaccine provided it meets the standard potency requirement

**Administration of antirabies vaccine** may give rise to local allergic reactions and to those of a general neuroparalytic nature The latter are caused by the presence of nervous tissue in the vaccine and occur most frequently during a repeated course of protective treatment No vaccine preparation is at present available which is free from the paralysis producing factor and therefore the administration of vaccine should be interrupted if even slight signs of dysfunction of the central or peripheral nervous system are observed By the same token antirabies vaccine treatment should not be given unless specifically indicated (see table)

**Control Measures** The majority of human exposures can be prevented by the use of control methods which will rid an area of enzootics or epizootics of rabies

The following measures should be applied in an efficiently organized rabies control program conducted by public health authorities: control of the canine population (registration restraint elimination of stray dogs) reduction in number of susceptible dogs by mass vaccination reduction in number of wildlife species which are a reservoir of the virus and continuous educational campaigns for the general public

## Coxsackie and ECHO Viral Infections

Since the discovery of Coxsackie viruses by Dall and Sickles in 1948 new viral techniques utilizing suckling mice and tissue cultures have led to the demonstration not only of twenty-four distinct Coxsackie serotypes but also of numerous other newly recognized viruses grouped together under family names such as ECHO viruses (twenty serotypes) and adenoviruses (eighteen serotypes). Other apparently new virus strains remain to be classified. Many if not most of the presently classified viral serotypes are prevalent infections of man

everywhere. The pathogenic activities of many of the sixty-two distinct serotypes are unknown; however, and some of the others are expressed as subclinical or very mild, easily overlooked illnesses. Because of their very high prevalence, multiple infections are frequent and spurious etiological associations are not uncommon. Some representatives of each group, however, have been definitely established as causes of clearly evident common illnesses. The illnesses caused by adenoviruses are discussed elsewhere (see p. 7).

**Coxsackie Viruses.** At the present writing the twenty-four distinct Coxsackie virus serotypes are separated arbitrarily into groups A and B on the

Illness Caused by Coxsackie and ECHO Viruses (Enteroviruses)

DISEASE	ETIOLOGY (Viral serotypes incriminated) (1958)	PREVALENCE AND CHARACTERISTIC OCCURRENCE (All are chiefly diseases)	DIFFERENTIAL DIAGNOSIS	COMMENTS
Herpangina (vesicular pharyngitis)	Coxsackie group A 2 4 5 6 8 10 (probably 3)	Most commonly as frequent sporadic illnesses in young children. Recognized mostly, however, in localized community and institutional epidemics.	Herpetic stomatitis with ulcerative pharyngitis  Summer fevers due to Coxsackie B, ECHO and adenoviruses.	Often called summer gripe or summer pharyngitis when characteristic pharyngeal lesions not observed.
Epidemic Pleurodynia (Bornholm disease)	Coxsackie group B 1 2 3 4 5	Mostly epidemic. Less common than group A in infections but recognized with greater frequency.	Acute medical and surgical emergencies — coronary occlusion, acute appendicitis, cholecystitis.	Most common in children but in isolated rural communities all age groups may be infected. Sequelae: orchitis, aseptic meningitis.
Aseptic Meningitis (nonbacterial meningitis)	Coxsackie A 7 9 Coxsackie B 1 2 3 4 5 ECHO 4 6 9 (14) (Polioviruses 1 2 3 also)	Enteroviruses are major cause of the aseptic meningitis syndrome in young children.	Aseptic meningitis due to mumps, herpes, lymphocytic choriomeningitis, arthropod encephalitis, poliomyelitis, viruses, leptospirosis.	Etiological diagnosis depends entirely on identification of viral cause.
Epidemic Exanthemata (Boston exanthem) (meningo-encephalitis with rash)	ECHO 9 ECHO 16	ECHO 9 — extensive epidemics of meningitis with rash reported throughout Europe in 1956. ECHO 16 — localized epidemics of Boston exanthem in U.S.A.	Common childhood exanthemata.	ECHO 9 also has the attributes of a Coxsackie group A virus.
Myocarditis Neonatorum (acute aseptic myocarditis)	Coxsackie B 3 and 4	Proved cases recognized chiefly in newborn nurseries and clinics. Intrauterine infection reported in one well-studied case.	Idiopathic myocarditis and sequelae of other viral infections.	Frequently fatal outcome. Associated with community epidemics of pleurodynia and aseptic meningitis.

basis of their differing behavior in mice. The nine teen group A viruses produce generalized myopathy in striated muscle and no other lesions in suckling mice. The group B viruses, on the other hand, produce in suckling mice fewer and less severe muscle lesions but produce in addition pancreatitis, encephalitis, hepatitis, and myocarditis. The group B viruses also produce pancreatitis (lysis of acinar cells) in adult mice, whereas group A viruses appear unable to grow and produce lesions in older mice. Recently two viruses, A 7 and A 14, have been shown to produce neuronal lesions in monkeys and the former has been incriminated by Russian workers as a possible cause of paralytic poliomyelitis in humans. While most group A viruses will not grow in monkey kidney cultures, which are commonly used for demonstrating and propagating ECHO and polioviruses, A 7, A 11, and the five group B viruses do grow in this tissue and produce somewhat similar cytopathogenic effects.

Besides their prevalence during the summer months, Coxsackie viruses resemble the poliovirus in other respects. They are very small and they occur in comparatively large amounts in oral secretions and in stools. They are resistant to antimicrobial drugs commonly used, germicides, and natural conditions unfavorable to the survival of most other viruses. Undoubtedly this accounts to some extent for their widespread occurrence in man and in his environment, particularly in sewage and on flies. Several strains have been found in mosquitoes.

**ECHO Viruses.** During a meeting of the WHO Expert Committee on Poliomyelitis (Geneva, July 15 to 20, 1957), it was observed that Coxsackie and ECHO viruses share certain properties with the polioviruses, such as size, seasonal incidence, and epidemiological patterns, and consideration was given to the concept that all viruses of similar size in the Coxsackie, ECHO, and poliovirus groups may be members of a single group of human enteroviruses. Thus these three groups of viruses may soon be officially regarded as separate genetic representatives of a single family of human viruses.

Representatives of the ECHO (enteric cytopathogenic human orphan) group of viruses share the following properties (Committee on the ECHO Viruses, National Foundation for Infantile Paralysis):

1. They are cytopathogenic for monkey and human cells in culture.
2. They are not neutralized by pools of the three types of poliomyelitis antiserum.
3. They are not neutralized by antisera for Coxsackie viruses that are known to be cytopathogenic in tissue culture and they fail to produce disease in infant mice.

It is interesting that ECHO 9 and 10 have been found since this report to produce Coxsackie-like lesions in suckling mice. Indeed, ECHO 9 was originally reported by several workers initially as an unidentified Coxsackie Group A virus. However, the virus was first classified as an ECHO 9 and will be so designated here.

**Illnesses Due to Coxsackie and ECHO Viruses.** The illnesses caused by Coxsackie and ECHO viruses occur chiefly but not entirely in young children during the warm months of the year. The illnesses are quite heterogeneous in their clinical manifestations. Perhaps the most common manifestation of infection in the very young, with both groups of viruses, is an undifferentiated febrile respiratory illness usually described nondescriptively as fever of unknown origin or summer gripe. However, certain serotypes are well established as causes of specific nosological clinical

entities such as *herpangina* and *epidemic pleurodynia*, and in addition such clinical syndromes as *aseptic meningitis* and *acute aseptic myocarditis* of the newborn. The most recent entity in which ECHO viruses have been incriminated is an epidemic exanthema occurring in outbreaks with and without associated aseptic meningitis. There is also evidence that certain ECHO and Coxsackie viral infections may be responsible for summer diarrheas in infants, however, their role in this symptom complex is still to be defined.

## HERPANGINA

(*Vesicular Pharyngitis*, *Aphthous Pharyngitis*)

**Definition.** Herpangina is a mild specific disease characterized by fever, lassitude, and small papular vesicular and ulcerative lesions in the soft palate and the faucial areas. Although it is one of the most frequent summer illnesses of early childhood, the specific nature of the illness in individual cases is often missed by the clinician. It is somewhat more often recognized when it occurs in epidemic form in newly established residential areas or in summer camps for children.

**History.** The disease was first recognized as a specific entity by Zahorsky in 1920. He suggested the name "herpangina" in a report of 80 cases in 1924. Reports of outbreaks of a similar illness in a summer camp and nursery school appeared in 1939 and 1941. The illness was not reported again until 1950 when certain group A Coxsackie viruses were suggested as etiological agents. Since 1950 the disease has been recognized with increasing frequency and viral studies have repeatedly confirmed certain group A viruses as etiological agents. Reports of the same agents found in association with similar illnesses in other countries leave little doubt that herpangina is a common occurrence in all parts of the world and that it is one of the most common manifestations of group A Coxsackie viruses.

**Etiology and Pathology.** Six strains of group A viruses have repeatedly been found causing herpangina (see table). The virus types found in herpangina, while immunologically distinct from each other, produce after brief incubation identical generalized destruction of the skeletal muscles of suckling mice and hamsters—followed promptly by death. No other lesions are observed. Mice over two weeks of age are completely resistant.

The pathology of herpangina in man is obscure. The illness does not result in death; consequently postmortem tissues are not available. Biopsies of muscle tissue from a typical case revealed neither pathological changes nor the presence of virus.

**Epidemiology.** The disease has been found during the summer months in nearly every community in which an effort to find cases has been made. Most illnesses occur in early childhood. As many as 10 per cent of children randomly selected from urban pediatric clinics have been found

FIG 11 Herpangina lesions

harboring herpangina strains of virus during July, August and September.

In a household or a neighborhood herpangina viruses rapidly infect nearly all intimate susceptible contacts including an occasional parent. However, even when under constant surveillance only about 30 per cent of those persons infected manifest typical faucial lesions. Nevertheless, a variable number of the infected family contacts will present a similar picture of mild febrile illness without the typical throat lesions. As in poliomyelitis and many other viral infections, a large proportion of the infections are not attended by any clinical manifestations.

Although immunity to the infecting strain appears permanent, the frequent presence of other strains in the community provides ample opportunity for a repetition of the typical illness within the same or a subsequent summer. Herpangina has been observed twice within one year in several children, each subsequent episode being caused by a strain different from that found during the initial illness. Most urban adults possess neutralizing antibodies against herpangina viruses; the number of types neu-

tralized increasing with age. Unlike age differences in sex and race have not been associated with observable differences in attack rates.

**Clinical Manifestations.** In a typical case the disease begins with a sharp elevation of temperature ( $102^{\circ}$  to  $105^{\circ}$  F). In the very young vomiting is common and convulsions may occur. The patient complains of headache and frequently of pain and tenderness in the neck, abdomen and extremities. Infants often salivate excessively and refuse food. Older children usually complain only mildly of a sore throat. During the first twenty-four to forty-eight hours the fever reaches its peak and only minute petechiae or papules may be observed on the soft palate and tonsillar pillars. Twelve to twenty-four hours later, two to six superficial ulcers with grayish bases surrounded by red areolae are observed at these sites (Fig. 11). The ulcerations heal within one to five days. Fever seldom lasts longer than three days and by the fourth day the patient is usually asymptomatic. There are no complications and a good immune response is produced. Hematological and cerebrospinal fluid studies have revealed no characteristic abnormalities.

**Diagnosis.** In a typical case a clinical diagnosis of herpangina is not difficult if a careful inspection of the pharynx is made, particularly when as frequently occurs there are similar cases in the household or the immediate neighborhood. Herpetic stomatitis occurs at all seasons of the year and is characterized by larger, more persistent and more painful ulcers in the anterior part of the mouth; lesions seldom occur exclusively in the pharynx. When laboratory facilities are available and suitable viral procedures can be carried out, differential diagnosis can be made by recovering either Coxsackie or herpes viruses from lesions or by demonstrating a specific rise in antibody titer. Unfortunately, few laboratories are at present in a position to perform such studies. Recurrent aphthae and Bednars aphthae seldom occur in the pharynx and are not usually associated with constitutional symptoms.

**Relation to Poliomyelitis.** The distribution and spread of herpangina parallels that of poliomyelitis and simultaneous infection with agents of both diseases is common. In a mixed epidemic a majority of persons infected with either or both of these agents can be expected not to show pathognomonic signs of specific illness and when they do show signs of illness characteristic of one agent, this fact does not exclude infection

with the other. Thus a clinical separation of herpangina without pharyngeal lesions from nonparalytic or "abortive" poliomyelitis without cerebrospinal fluid abnormalities may on many occasions be extremely difficult if not impossible. Even laboratory efforts to unscramble mixed outbreaks are liable to encounter insurmountable difficulties unless accompanied by exhaustive epidemiological studies.

**Prognosis.** The disease tends to run a mild course; it may occasionally seem more severe in an adult. No complications or deaths have been reported. The ability of the physician to recognize this illness and give a hopeful prognosis is much appreciated by parents worried about poliomyelitis, often occurring at the same time in the community.

**Treatment.** None of the antimicrobial drugs appears to influence the severity or the duration of herpangina. Symptomatic treatment is often efficacious and should be used when indicated.

#### EPIDEMIC PLEURODYNIA

(Bornholm Disease Epidemic Myalgia Devil's Grip)

**Definition.** Epidemic pleurodynia is an acute specific viral disease characterized by sudden onset of severe paroxysmal pain in the region of the attachment of the diaphragm which is aggravated by respiration and accompanied by intermittent fever, headache, anorexia and malaise. Because they are uncommon except during epidemics the specific nature of such alarming symptoms occurring abruptly in previously healthy persons often is not recognized.

**History.** The disease was first described by Daase and Homann in Norway in 1872. Although Finzen observed the disease in Iceland as early as 1856 he did not publish these observations until 1874. In 1888 Dabney described the first outbreak in the United States. Following extensive observations of this disease on the Island of Bornholm Sylvest in 1933 published a monograph reviewing all previous reports thus stimulating much interest in this disease. Numerous reports of outbreaks in England and the United States followed. Although viral etiology was postulated by many observers all efforts to demonstrate such an agent failed until 1949 when a Coxsackie virus type B1 was found in relation to sporadic cases in Connecticut.

**Etiology and Pathology.** All group B Coxsackie viruses have been confirmed as etiological agents of epidemic pleurodynia (see table). The specific pathology of this disease in man is unknown since a post mortem examination has never been reported. The occurrence of high fever and the demonstration of Coxsackie B type viruses in throat secretions and stools suggest a generalized infection.

**Epidemiology.** Most reports of epidemic pleurodynia have come from Europe and the United States where outbreaks have been described over wide geographical areas. Strictly a summer and early autumn disease, the illness occurs in all age groups but is most common in children and young adults. Long-lasting immunity against the infecting strain of virus results. Although endemic areas have occasionally been described, pleurodynia is not generally prevalent each summer and most reports deal with sharp outbreaks confined to geographically limited areas.

Most evidence suggests person-to-person spread and multiple cases frequently occur in a household. The incubation period appears to be three to five days. Many apparently susceptible household contacts may escape infection. Unlike group A infectious infection with a group B virus is nearly always associated with a clinically apparent illness, not always, however, in the form of typical pleurodynia.

**Clinical Manifestations.** The disease begins with sudden onset of pain in either the abdomen or the chest. Although fever is variably follows in all cases, it is pain in the epigastrium often shifting to the lower part of the anterior thorax on either side which is the most characteristic manifestation of epidemic pleurodynia. The pain is frequently so extreme that the patient seems on the verge of collapse. He is observed breathing rapidly and shallowly, leaning forward and to one side, splinting his chest by holding one arm tightly against it. It is obvious that both movement and respirations aggravate the pains. The physician faced with such a spectacle is moved to administer analgesics or opiates promptly unless a surgical emergency is suggested. In either case arrangements for hospitalization may be made—then cancelled within the hour because the patient rather suddenly feels well—all negotiations to be reopened a short time later by recurrence of severe pain. After several such attacks the patient becomes extremely apprehensive of future exacerbations and is usually content to remain in bed for several days. The patient often has difficulty describing his pain accurately, localizing it over the area of the epigastrium and in the region of the attachment of the diaphragm. Very often the patient expresses his difficulty by saying "I can't breathe" or "It hurts to breathe," indicating a feeling of constriction in the chest—a feeling which undoubtedly led to the early American designation "Devil's grip" for this disease. The pain is described

as a dull ache like a toothache, occasionally as a stabbing pain. Children are usually restless with knees drawn up, their sobbing or crying jerkily interrupted by painful stitches. Convulsions are common in infants during bouts of high fever. Moderate tenderness in the affected area is often accompanied by hyperesthesias, localized muscle swellings and altered reflexes, the latter most often in the abdominal areas.

*Fever* a constant finding during the initial attacks may occasionally exceed 104° F but usually will fluctuate from 101° to 103° F. The fever is intermittent, recurring usually during exacerbations of pain. Other prominent symptoms are headache, sore throat and malaise. Nausea and vomiting occur during the early stage of illness in young children; however, the severe pain tends to suppress excessive vomiting. Although pleural rubs are occasionally reported, there appears to be no evidence of lung involvement and coughing is conspicuously absent. Hematological findings are usually within normal limits. Relapses may occur a few days after apparent recovery and may continue to occur over a period as long as a month.

**Complications.** Orchitis lasting three to seven days appears to be the complication most frequently reported, occurring in nearly all large outbreaks. Fibrinous pleuritis is irregularly reported but it is not uncommon. Aseptic meningitis has been reported as an infrequent complication, perhaps more often as associated illnesses observed during pleurodynia epidemics (see Aseptic Meningitis below).

**Diagnosis.** A clinical diagnosis is seldom difficult once the existence of an epidemic is apparent. However, during the early stages of an epidemic or when only sporadic cases are encountered, the occurrence of severe pain in the chest or abdomen may suggest serious medical or surgical emergencies. This impression is often reinforced when the disease occurs in older persons, perhaps with a previous history of cardiac disease or in children when attended by fever, nausea and vomiting. Fortunately, in the former instance, the moderately elevated but otherwise normal pulse plus the shifting character of the pain will suggest the proper diagnosis. In the latter instance, the absence of deep-seated tenderness, the presence of superficial hyperesthesias of the skin and the usually early remissions of pain are helpful in differentiating pleurodynia from acute appendicitis. Since herpangina may also be prevalent and in children may be characterized occasionally

by abdominal pain, careful inspection of the pharynx and faucial areas will be helpful in making a correct clinical diagnosis. It should be noted, however, as described below, that certain Coxsackie B viruses can cause severe, sometimes fatal myocarditis in the newborn.

**Laboratory diagnosis** is made by demonstrating Coxsackie group B viruses in the stool or throat washing taken during or shortly following the acute illness. A rise in specific neutralizing antibodies against one of the group B viruses during the illness and convalescent periods provides evidence for infection concomitantly with the illness. As with the group A viruses, the complement fixation test for antibodies, although apparently group specific, may give nonspecific reactions within the Coxsackie group and is chiefly of use in confirming that a Coxsackie infection occurred.

**Prognosis and Treatment.** Despite its sometimes stormy course, virtually no deaths have been attributed to the uncomplicated disease. There is no specific treatment for the disease or its complications. Modern antimicrobial drugs are ineffective against the Coxsackie viruses. Symptomatic relief from pain and high fever usually can be achieved by analgesics and antipyretics. Opiates are occasionally required to alleviate severe pain. Rest in bed is, of course, mandatory during the period of pain and fever. Too rapid return to normal activity seems associated with more frequent sequelae, particularly orchitis and meningeal disease.

#### ASEPTIC MENINGITIDES\* DUE TO COXSACKIE AND ECHO VIRUSES

Certain Coxsackie and ECHO viruses represent the most recently established causes of this clinical syndrome, an entity already characterized by the variety of its multiple causations. No less than eleven Coxsackie and ECHO serotypes have been incriminated (see table). At least ten other distinct infections (see Nonpurulent Meningitis, p. 175) are associated with aseptic meningitis, the most common of which are nonparalytic poliomyelitis (three serotypes), mumps, lymphocytic choriomeningitis and herpes virus infections. It is now apparent that Coxsackie and ECHO virus infections together with nonparalytic poliomyelitis are responsible for a large number of the aseptic meningitis cases observed in infants and young children, whereas other agents are more likely to be responsible in adults. The epidemiology of aseptic meningitis due to enteroviruses is similar to that of polio

myelitis herpangina and epidemic pleurodynia

**Clinical Manifestations** Aseptic meningitis due to ECHO and Coxsackie viruses are clinically indistinguishable from each other and also from nonparalytic polio myelitis (see Poliomyelitis p 63). Rhodes reviewed the clinical features of eighteen cases of aseptic meningitis due to Coxsackie B viruses observed from 1951 to 1955. The average age was 6 years (range 3 to 11). The clinical features consisted of fever, signs of meningitis, nausea and vomiting, headache, drowsiness and pain in the neck and back in most cases. Although seven patients complained of myalgia, none had signs of meningitis, nausea and vomiting or paralysis. Only two patients had cerebrospinal fluid cell counts higher than 500 per cu mm; the average was 188 cells per cu mm. Sugar and chloride values were normal and protein values did not exceed 45 mg per 100 ml.

**Diagnosis** The clinical diagnosis of the aseptic meningitis syndrome is considered in the sections on Nonpurulent Meningitis p 176 and Poliomyelitis p 64. A specific etiological diagnosis of Coxsackie or ECHO infection depends on isolation of the causative agent (usually from throat or stool specimens) and the demonstration of an antibody response in complement fixation or neutralization tests. At times the agent may be isolated directly from the cerebrospinal fluid.

**Pathology** No uncomplicated cases of aseptic meningitis due to Coxsackie and ECHO viruses have been reported at autopsy; however, several fatal cases of myocarditis neonatorum due to Coxsackie B viruses, types 3 and 4, also showed cerebral lesions. Two of these cases had pathological signs of aseptic meningitis and two of focal encephalitis. Kibrick describes one case in which the spinal cord and meninges revealed edema and a diffuse infiltration with moderate numbers of macrophages and occasional polymorphonuclear leukocytes. Areas of encephalitis were seen in the cerebellum and pons and degenerative and inflammatory lesions were particularly numerous in the spinal cord involving the anterior horns and reticular formations.

**Prognosis and Treatment** Coxsackie and ECHO virus meningitis is apparently uniformly nonfatal (after the neonatal period), having a more benign and shorter course than other forms of aseptic meningitis. Although less common, the illness tends to be somewhat more severe in adults.

Because it is impossible to exclude the presence of polioviruses or other more severe viral infections of the central nervous system during the acute stage of illness, treatment performed must follow that prescribed for the preparalytic period in polio myelitis (see p 65). Prognosis for the same reason must be guarded.

#### EXANTHEMATA AND "ASEPTIC MENINGITIS WITH RASH" DUE TO ECHO VIRUSES

In 1954 Neta and Enders reported a new virus now classified as ECHO 16 in association with a benign rash disease subsequently called "Boston exanthem." The same virus was later found in relation to a similar outbreak in Pittsburgh. No central nervous system involvement was observed in either outbreak. During the first outbreak in Boston, however, ECHO 16 was also found by Kibrick in eight hospitalized persons with aseptic meningitis, none of whom had rash.

In 1956 a widespread epidemic illness occurred on the continent of Europe in England and in Canada, described variously as "meningitis with rash," epidemic exanthem with meningitis, and "lymphocytic meningoencephalitis with myalgia and rash." ECHO 9 virus was recovered from each of these outbreaks as well as from a previous outbreak in Italy in 1955 (aseptic meningitis without rash) and a subsequent one with rash in Wisconsin in 1957.

The illness as generally observed appeared to fit the picture of uncomplicated viral meningitis and the associated rash which usually appeared one to three days after onset of fever was described in some cases as maculopapular and rubelliform and in other cases as blotchy and morbilliform. Vesiculation followed some of the more severe eruptions. No deaths were observed.

The ECHO 9 virus strains associated with these outbreaks were isolated both in monkey kidney cultures and in suckling mice and were reported variously in different studies as ECHO virus and as a new Coxsackie A virus. However, since all the strains isolated seem identical with a virus already classified as ECHO 9, this term is most generally used.

#### MYOCARDITIS NEONATORUM

(Epidemic Myocarditis of Newborn, Acute Aseptic Myocarditis)

Evidence that Coxsackie B viruses, types 3 and 4, may produce severe even fatal myocarditis in the newborn was presented

in several excellent reports appearing in 1955 and 1956. Fourteen fatalities were observed in a total of twenty cases reported from Southern Rhodesia, Amsterdam and Boston. In most cases infection undoubtedly occurred after birth; however, several infections may have occurred *in utero*. Pathological examination revealed diffuse and focal myocarditis characterized by degeneration of myocardial fibers and infiltration by macrophages and leukocytes. Aseptic meningitis and focal encephalitis were also observed in several fatal cases.

### PREVENTION OF COXSACKIE AND ECHO VIRUS INFECTIONS

The success of the Salk poliomyelitis vaccine offers hope that effective Coxsackie and ECHO vaccines can be produced. However, the need and demand for them are as yet undefined.

## Poliomyelitis

### (Infantile Paralysis)

**Definition.** Poliomyelitis is a common acute viral disease characterized clinically by a brief febrile illness with sore throat, headache and vomiting and often with stiffness of the neck and back. In many cases a lower neuron paralysis develops in the early days of illness.

**History.** References to conditions which may have been poliomyelitis date from earliest times, but no descriptions of this disease have been found in medical literature before the end of the eighteenth century. At this time mention of acute paralysis in childhood was made in England by Michael Underwood in his textbook on diseases of children. During the subsequent fifty years there were several descriptions of poliomyelitis, the best being that by the German orthopedist Heine, which was published in 1840. During most of the nineteenth century the disease was regarded as a sporadic and ubiquitous affliction of young infants. Its contagious and epidemic character did not receive emphasis until Medin's work appeared in Sweden in 1890. From that time forward the disease ceased to be a curiosity and became a periodic scourge in some countries. The principles of its epidemiology were first reviewed by Medin's pupil Wickman, who published his monograph in 1908, the same year in which Landsteiner discovered the virus.

**Etiology.** The virus of poliomyelitis has been commonly isolated from patients acutely ill with this disease; the best sources being intestinal excreta, the oropharynx, occasionally the blood, and at necropsy the central nervous system. It is extremely small, as viruses go. It is labile in some respects, being sensitive to drying and heat at pasteurization temperatures and stable in others, resisting ether and certain other so-called disinfectants. The virus remains viable at icebox temperature in aqueous suspensions of feces for months and in pieces of infected spinal cord for years when stored in 50 per cent glycerol.

Man is the animal most susceptible to the virus; chimpanzees and cynomolgus monkeys come next, and after these come the other primates. However, infection of mice and other rodents has been achieved, particularly with Type 2 strains. A fundamental discovery by Enders, Weller and Robbins (1949) has been the demonstration that polioviruses will grow in tissue culture and give rise to cytopathogenic changes whereby their presence can be recognized. As a result of the practical application of this method, the isolation, typing, neutralization, antigen and vaccine production of polioviruses are almost universally carried out *in vitro*.

Within the poliovirus family there are three immunological types (1, 2 and 3). It has been shown repeatedly in the laboratory that although *type specific immunity* can be induced an animal can be reinfected and paralyzed with an *heterologous type* of poliomyelitis virus. This is the reason usually given to explain why the same person may contract paralytic poliomyelitis more than once. Repeated subclinical or inapparent infections due to the same type of poliovirus may and probably do occur quite often in man.

**Epidemiology and Pathogenesis.** Poliomyelitis is an endemic and epidemic disease of world wide distribution primarily affecting children and spread by *contact* with clinical and inapparent "cases" acting as carriers. Although regarded as a contact disease, there is still much to be learned as to how this disease is actually transmitted. Some of the present mystery vanishes however with the recognition that unlike certain other contact diseases such as measles in which the disease passes from one recognized case to another, the spread of poliomyelitis often occurs through the medium of mild cases, many of which are so mild as to escape recognition. Evidence is convincing that during an average epidemic of poliomyelitis those who are ill enough to be diagnosed or become paralyzed represent a small fraction of those who become infected. Nevertheless the contact theory does not cover the whole story for it does not explain why cases of poliomyelitis occur at a much higher rate in the summer and early autumn than in the winter. There are two possible explanations: either something happens in summer which enormously facilitates the dissemination of the virus throughout a community or something happens which makes people far more susceptible.

Poliomyelitis virus has been found under natural circumstances in sewage and on food (contaminated by flies) and in flies and cockroaches during epidemics. An obvious question is whether the patient's immediate or remote environment is not only contaminated but infectious, serving to spread the disease through the agency of contaminated water, food or insects. However, there is at least no evidence that insects are an *essential link* in the chain as are mosquitoes in the transmission of malaria or yellow fever.

Children are more susceptible to poliomyelitis than are adults. As in measles, this is an expression of acquired immunity on the part of the adult populations. The age

at which this immunity is acquired differs in different places. In the United States, although most of the cases fall within the age group of four to fifteen, some 25 per cent or more of the cases now occur in young adults and this percentage is rising.

How the virus of poliomyelitis actually enters the human body is a subject of controversy. It is unlikely, however, that it gains access to the central nervous system directly by way of the nasal mucosa and the olfactory bulbs. It is more likely that it penetrates through the mucosa of the oral cavity, the alimentary tract or conceivably the skin. Very early in the disease or late in the incubation period the virus has been recovered from the blood stream but the central nervous system, the oral cavity and the intestinal tract are sites for which it has affinity and where it soon settles (see Fig. 12).

Prior to, during and after an acute attack, virus can be demonstrated in the oropharynx and in the intestinal tract. In the former site it persists for about ten days from onset and in the latter for about three to six weeks or even longer. This (acute and convalescent) carrier state can be initiated by an attack so mild as to go undiagnosed or even unnoticed. Although usually not more than one person in a family becomes paralyzed at a single time, simultaneous multiple infections within families are common. Evidence suggests, however, that in certain families a high prevalence of the paralytic form of the disease has prevailed through several generations.

As to *predisposing influences*, recent tonsillectomy (performed within three months of onset) is regarded as one. During epidemics this operation has been followed by bulbar poliomyelitis more often than might be expected. Furthermore, such minor procedures as inoculations for diphtheria or pertussis also fall into this category. Severe exertion or stress or an injury if sustained on the day or two preceding or following the onset of acute poliomyelitis tend to make the prognosis less favorable. Pregnant women are quite vulnerable to poliomyelitis. They are also subject to higher than average rates of exposure when there are young children in the family.

**Morbid Anatomy.** Important lesions occur in the central nervous system, notably in the gray matter of the spinal cord. Hypertrophy of lymph nodes (cervical, axillary and mesenteric) also occurs. Myocarditis has been described in fatal cases.

Classic neural lesions are the result of

FIG 12 Upper panel Diagram illustrative of various clinical forms which poliomyelitis may assume. The stippled areas indicate periods of fever. The time scale in days starts with the hypothetical day of exposure.

Lower panel The presence of virus and antibodies as related to the clinical course of the infection.

the neuronotropic character of the virus. Ganglion cells in the anterior horns of the spinal cord are characteristically involved, particularly in the cervical and lumbar regions. These lesions pass through stages marked by diffuse chromatolysis, destruction of neurons, neuronophagia, and perivascular and interstitial infiltration of round cells. The brain stem is nearly always involved in fatal cases, whereas lesions of the cerebral cortex are restricted to the precentral gyrus (motor area).

**Pathological Physiology.** Although physical signs attributable to a disturbance within the central nervous system can often be explained on the basis of a diffuse inflammatory reaction in acute poliomyelitis, a correlation between direct nerve cell injury and the physical sign should be considered first before incriminating the accessory influences of edema or other secondary factors. Since muscular function is often regained in previously paretic muscles during convalescence, this would seem to indicate that the changes in certain virus-infected cells are reversible. Illustrative of the reversible affections are the transient paresis of the urinary bladder and the intestinal tract.

The occurrence of spasm in paralytic and nonparalytic muscles has been the subject of extensive discussion. Some investigators consider it to be due to increased

myotatic reflex activity, others to reflex contraction secondary to pain in hyperirritable muscles.

**Incubation Period.** Usually stated as about ten days, the incubation period is actually less. It may range from as short as three to as long as thirty-five days. Average figures indicate nine to thirteen days for paralytic cases and three to ten for abortive cases, the difference being that first phase symptoms may be so slight as to escape notice. Opinions differ as to the best method of dating the onset of the disease. It is the writer's practice to consider the earliest (first phase or minor illness) symptoms when present as marking the onset of the disease.

**Symptoms.** Common clinical forms which poliomyelitis may assume are illustrated in Figure 12. Clinical terms for the designation of various forms of infection with polioviruses have included the following: *inapparent infection* (asymptomatic infection) which is the commonest form of infection with polioviruses and is diagnosable only with the assistance of laboratory tests; *abortive poliomyelitis*, a somewhat non-specific term indicating that although the infection did not progress beyond the minor illness, the clinical and/or laboratory evidence was sufficient to warrant a diagnosis of poliomyelitis; *paralytic poliomyelitis*, which may be of the spinal bulbar

or cranial nerve types \* and *encephalitis* due to polioviruses. Previously the term of *nonparalytic poliomyelitis* was employed but a recent recommendation from the World Health Organization (1957) has called for its elimination and the substitution of *aseptic meningitis* qualified as follows (poliomyelitis probable) or (etiology unknown) or (due to poliovirus type 1 2 or 3) or (due to mumps Coxsackie or ECHO viruses etc.) For the identification of the last named infections laboratory tests are required. By this nomenclature cases of proved poliomyelitis with the diagnosis confirmed in the laboratory will be so recorded and cases of unproved etiology will not be designated as poliomyelitis unless the clinical indications are very strong. Those which are due to other agents will perhaps be more properly recorded. The necessity for this change stems from the fact that prior to the wide scale use of the Salk type vaccine in the United States not more than 50 per cent of so-called nonparalytic cases of poliomyelitis were actually poliomyelitis. It is possible that a still higher percentage will be erroneously designated if the loose term "nonparalytic poliomyelitis" continues to be used.

*"The Minor Illness"* These brief illnesses so commonly seen during poliomyelitis epidemics usually last only 24 hours and are more frequent in children than in adults. They are the clinical indications that infection has started and are probably contemporaneous with the period of viremia but they cannot be diagnosed with certainty by clinical methods. Clinical manifestations include fever headache vomiting listlessness sore throat and rarely diarrhea. Sore throat is a much more frequent complaint in the minor as opposed to the major illness and thus becomes a useful symptom in determining the stage of the disease. The cerebrospinal fluid findings are almost always normal here and the symptoms comparable to those of a variety of mild acute illnesses. A tentative diagnosis can be made however on those patients who have been in close association with a recognizable case of poliomyelitis. For a positive diagnosis virus isolation or antibody tests are almost essential.

The minor illness in poliomyelitis may

\* A clinical definition of *paralytic poliomyelitis* is that the patient must have clearly demonstrable paralysis as opposed to transient weakness. This paralysis of the flaccid type should be recognized preferably by more than one physician on two consecutive physical examinations performed at least 24 hours apart or better still during the acute stage of the illness and during convalescence.

or may not be followed by the major illness. In the latter event it is also known as *abortive poliomyelitis*.

*The "Major Illness"* This term relates to aseptic meningitis and paralytic poliomyelitis. It designates that important complication of acute poliomyelitis which may occur with or without antecedent symptoms and which indicates that lesions have developed within the central nervous system to an extent sufficient to give rise to neurological symptoms. The onset may be abrupt or gradual over a period of several days. If the onset is sudden fever vomiting and severe headache are again commonly encountered. These early symptoms may be accompanied or followed quickly by spontaneous pain in the extremities—deep pain hyperesthesia and sometimes paresthesia. Soreness and stiffness of the neck and back and hamstring muscles become prominent early. Severe lumbar back pain not associated with motion of the spine (in fact relieved by motion) is relatively common in adults with severe infections. Abdominal pain may also occur.

If "major illness" symptoms develop insidiously as is often the case with adults there may be no fever at first or only slight fever not above 100° F. This gradual onset may be puzzling and responsible for a delay in diagnosis. Such patients appear uncomfortable and restless rather than sick. They complain of listlessness intermittent headache anorexia with occasional vomiting pains in the extremities and again hyperesthesia and paresthesia followed by stiffness of the neck and back and pain in the back.

During the febrile period temperatures may range from 100 to 103 F depending on the age of the patient and may last three to ten days. The onset of weakness or flaccid paralysis usually occurs while fever is still present but may appear as the fever begins to fall. Thus concurrently with an improvement in the systemic clinical picture the patient discovers that his limbs will not function properly. Acute retention of urine is not uncommon particularly when severe paralysis of the lower extremities is present. Constipation or obstipation is also common.

*Spinal Paralytic Poliomyelitis* This is the classic form of poliomyelitis in which the presence of flaccid paralysis makes the clinical diagnosis quite definite. Muscles commonly paralyzed in order of frequency are those of the legs (by far the most frequent) arms back thorax face intercostal region and diaphragm.

**Respiratory Paralysis** Difficulty in breathing results from several causes which will be considered later

**Encephalitic Symptoms** These occur at any stage and in some epidemics are very frequent. Symptoms include dizziness which is not true vertigo but rather a lightheadedness, apprehension, yawning, twitching of the limbs and irritability followed by lassitude, drowsiness and even coma. Convulsions are rare.

**Bulbar Paralysis** The bulbar form is most serious. It includes those cases in which cranial nerve nuclei are involved. When the tenth (and often the eleventh) cranial nerves are implicated there is unilateral or bilateral weakness of the soft palate which sags unnaturally in the back of the throat. There may also be weakness of the pharynx and vocal cords. This results in an inability to swallow or to talk clearly and occasionally in regurgitation of fluid through the nose. Other patients have symptoms and signs indicating involvement of the autonomic centers of the medulla, notably the respiratory center. Respiratory failure may progress with great rapidity.

**Diagnosis** Initial symptoms and signs of the acute disease are likely to be nonspecific. Often a preliminary diagnosis is tonsillitis or summer gripe. An important point of differentiation is that signs indicating respiratory tract involvement other than sore throat are absent. If the disease progresses stiffness of the neck, back and hamstring muscles soon becomes prominent. At this stage there is apt to be an increase of cells and protein in the cerebrospinal fluid. These clinical and laboratory findings are again not specific for poliomyelitis, being essentially those of a benign aseptic meningitis which may be due to a variety of agents of viral, bacterial, spirochetal or even protozoan origin. Thus it may not be possible to make a positive diagnosis of aseptic meningitis (due to poliovirus) without resort to virological or immunological tests. In the absence of such tests the term aseptic meningitis (poliomyelitis suspected) is recommended.

Nevertheless stiffness of the back is a characteristic sign of poliomyelitis. It is best elicited with the patient sitting up in bed with the knees naturally flexed and asking him to "kiss his knees." If the back is stiff, attempts to do this will cause pain. Tightness and soreness of the hamstring muscles and resistance to extension of the leg are common.

The reflexes in early stages of the "major illness" may be normal and active. Later, if

the onset of paralysis is imminent there is an irregular shift of hyperactivity and then sudden (and sometimes transient) shifts to diminished (or absent) reflexes. Usually the appearance of reflex changes precedes the appearance of weakness or paralysis by twelve to twenty-four hours. Superficial reflexes, i.e. the abdominal cremasteric and spinal reflexes, are the first to disappear.

Although the periodic but cautious examination for muscle power is part of the daily examination of the patient, all patients should be spared from exhaustive and exhausting muscle examinations during the acute stage of the disease. Patients in whom there is progressive muscle weakness, however, require frequent observation for evidence of diminished excursions of the intercostals and diaphragm.

A valuable laboratory test is the examination of the cerebrospinal fluid. If the (white) cell count is elevated above 8 cells per cu mm and the protein is above 35 mg per 100 ml, the diagnosis in a suspicious case is more likely, but one cannot rely on a negative test to exclude poliomyelitis. Furthermore, there is an element of timing because during the minor illness a normal cerebrospinal fluid may be expected. One should also recall that these positive findings are those of aseptic meningitis of other etiology. The cerebrospinal fluid cell count is likely to be highest during the first week of the major illness, and although the predominant cell type is usually mononuclear, early in the disease polymorphonuclear forms predominate. Usually the white cell count does not exceed 300 cells per cu mm. The protein content of the fluid is low and often normal during the first week but rises later, remaining up through the fourth week and then gradually decreasing to normal. Thus a high and rising protein content may exist after the cell count has returned to normal, a picture often confused with the Guillain-Barre syndrome.

There is no consistent change in the peripheral blood picture. As a rule the total leukocyte count is only moderately elevated (10,000 to 16,000 per cu mm) with relative lymphopenia. Rapid erythrocyte sedimentation rates have recently been reported in about half the patients tested. Routine urinalysis reveals no abnormalities. For the isolation of poliovirus, tissue culture techniques are now available in many laboratories. Stool specimens are usually the best source of virus.

Serological tests (neutralization and com-

plement fixation tests) which can be done on matched (early and convalescent) blood samples for purposes of clinical diagnosis are becoming of increasing value. Their availability is likely to increase.

**Differential Diagnosis.** Paralytic poliomyelitis should be considered whenever flaccid paralysis (particularly paralysis without sensory changes) occurs in the presence of fever and in the absence of traumatic or other types of injury to the cord. It can be confused with the summer arthropod borne encephalitides but serious paralysis of the limbs does not usually occur in those conditions.

Poliomyelitis without paralysis (aseptic meningitis) offers great difficulty in diagnosis without the aid of laboratory tests. This picture can be confused with mumps encephalitis particularly when mumps occurs without involvement of the salivary glands and with postmeasles encephalitis, meningoencephalitis (of undetermined type), lymphocytic choromeningitis and infectious neuronitis (Guillain Barre syndrome). Infections by members of the Coxsackie group and ECHO group of viruses may be easily mistaken for poliomyelitis as may also leptospirosis.

Rheumatic fever is often diagnosed as poliomyelitis. Other conditions which have been confused are acute meningitides (of various types) and tuberculous meningitis. In these conditions the diagnosis is likely to become apparent in the course of time. More rarely acute osteomyelitis, trichinosis, acute appendicitis, infectious mononucleosis and lead poisoning are mistaken for poliomyelitis.

It is also well to recall that generalized weakness of limbs may occur in the presence of acute fever as in influenza or acute enteritis.

**Prognosis.** During the early and acute stage of poliomyelitis predictions as to eventual outcome are risky. Extreme agitation, restlessness and apprehension in the febrile stages may indicate a poor prognosis and if physical exertion has been undertaken in the early days of illness (in the major illness) a less favorable result can be expected. The height of fever bears little relationship to the extent of paralysis which may ensue but the duration of high fever may be significant.

The mortality rate for any given epidemic will vary according to diagnostic criteria. It may range from 1 to 1 per cent or higher. By far the highest mortality occurs in bulbar cases. The severity of the

illness and the case fatality rate increase with the age of the patient.

Paralysis shows a remarkable tendency to improve in this disease but the extent of recovery is subject to variables and primarily to the degree of irreversible change which the virus has inflicted on the infected nerve cells.

The rate of recovery of strength in individual muscles or muscle groups follows a fairly definite pattern. By the end of the third month from the onset a muscle will usually recover approximately 60 per cent of the total strength that it will ever recover under treatment. During the next three months an additional 20 per cent may return. After this the recovery rate becomes increasingly slower so that by the end of eighteen months of treatment it is more than likely that little increase in muscle strength can be expected.

**Treatment.** At present no specific treatment is available for poliomyelitis. None of the antimicrobial drugs which have been tried has any effect in destroying the virus or controlling its spread within the body.

Guiding principles of therapy depend upon the type of case: the mild case with out paralysis, the paralytic case and the life threatening case. Only in the latter two will the services of specialists be required. In the life threatening case adroit management and a team of specialists may be necessary.

**Mild Cases.** It is impossible to determine within the first few hours or days of illness whether a given case will or will not go on to the eventual development of paralysis. But the clinician's responsibility in the management of these early though potentially severe cases seems clear. Thus during epidemics all patients with brief febrile illnesses of the type described above deserve to be regarded with suspicion. Physical activities should be curtailed and the patient should be kept quiet and in bed under observation preferably at home for at least a week. Seldom do they require special types of therapy such as drugs, hot packs, orthopedic care or physiotherapy. Potentially such patients may be infectious and therefore require some degree of isolation. In a small percentage of these patients some degree of paralysis usually mild may develop during the postfebrile stage. For this reason such patients should be followed for at least three weeks.

**Paralytic Cases.** Hospitalization is advisable for paralytic cases. An isolation hospital is not necessary for general hospitals.

can care for poliomyelitis patients provided isolation precautions can be carried out. Care should be exerted that the trip to the hospital involves a minimum of exertion and trauma. Within a large hospital the management of a patient with acute and advancing paralysis often involves the services of a team composed of a physician (internist or pediatrician), an orthopedic surgeon, a physiotherapist and perhaps specially trained nurses.

**GENERAL MEASURES FOR THE CASE WITH MYELITIS** Orthopedists recommend that a hard bed be provided from the beginning. The bed should be fitted with a footboard placed several inches beyond the mattress allowing room for the heels or toes when the patient lies supine or prone. If the legs are weak the knees should be supported in a slightly flexed position; weak arms should be in external rotation alongside the body but not against it.

Early in and during the stage of active myelitis (in which fever is usually present) there are four important aspects of general therapy: adequate rest, cautious use of sedation and analgesia, adequate fluids and proper nursing care.

For all patients, whether at home or in the hospital, *early bed rest* is important. As part of the program of rest the patient should be spared from extensive and repetitive physical examinations, undue fatigue and from injections which are not essential.

*Sedation* and other means for the relief of pain are important considerations. Relief may be aided by the intermittent application of hot moist packs. Numerous types of these packs have been advocated. Two general types are in current use: the so-called "wrap around pack" and the "lay on pack." Woolen cloth is favored material. Both types of pack call for application directly to the skin of the hot wet wool from which the water has been well wrung. This is then covered by two additional layers, one of which is of waterproof material and the second is for insulation.

The response to common analgesics and sedatives is not very satisfactory in early stages, but sedatives are often used. Often if pain is relieved by hot packs, drugs will not be necessary. This is desirable for the danger of aggravating incipient or actual respiratory difficulty makes it necessary to use sedatives cautiously.

Although several drugs have been advocated for the relaxation of muscle tightness and relief of pain, it would seem that they are not as effective as the more cumbersome method of hot packs.

Fluid should be given freely and when ever hot packs or hot baths are used, salt tablets should be added to make up for excessive salt loss in perspiration.

**Nursing care for the acute disease** should follow general principles used in acute infections. The diet should be light. Isolation technique with so-called typhoid precautions should be followed for one to three weeks depending upon local rules. The patient's stools should be disposed of as quickly and safely as possible. The use of a chemical disinfectant to sterilize the stools is not recommended.

**CARE OF PARALYZED LIMBS** Protection of the recently paralyzed limb (rather than fixation) is the objective. The ultimate care of such limbs is essentially an orthopedic problem and consequently will not be discussed here.

**COMPLICATIONS** *Urinary retention* is common in patients with severe involvement of the lower extremities. Before resorting to catheterization, an adequate trial of drug therapy should be given. The parasympatheticomimetic drug, furfuryl trimethylammonium iodide (Furmethide) has proved efficacious if given subcutaneously in adequate dosage. In infants, doses of 1.25 mg (0.3 to 0.5 ml) have been used. In children the dose has ranged from 2 to 5 mg; in adults from 5 to 7 mg. If there is no response, catheterization is indicated together with prophylactic antimicrobials. In general, urinary retention is a complication that lasts but a few days.

**Life-Threatening Poliomyelitis** **BULBAR POLIOMYELITIS** Loss of ability to swallow is the most common cause of respiratory tract obstruction in poliomyelitis patients. Steps involved in treating this condition begin with *postural drainage* to maintain a free airway with the bed tilted at an angle of 10 to 12 degrees off horizontal. Patients are usually more comfortable in a side-lying than a prone position. When mechanical aspiration is done, a rubber or polyethylene catheter may be passed through the nose into the hypopharynx. The catheter is then connected to an electrically driven suction machine or water pump; the ideal is to provide gentle intermittent suction. If swallowing is impaired, fluid, salt and nutrients are administered either by hypodermoclysis intravenously or by proctoclysis. The amount of fluid depends on the age, size and condition of the patient. 3000 ml or more are recommended daily for adults. Intravenous saline and glucose should be given slowly and in small amounts, not more than 500 ml at a time.

*Respiratory difficulty* may reflect at least four types of disturbances. In any given case of poliomyelitis several of them may coexist but it is important to recognize which are involved. They are (1) Disturbance of function of the muscles which perform the respiratory movements (2) Disturbances of the central control of respiration so that damaged neurons do not respond in the normal manner to changes in the CO<sub>2</sub> concentration pH and O<sub>2</sub> saturation of arterial blood (3) Obstruction of the airway caused by inability to swallow and by paralysis of intrinsic muscles of the larynx aspiration of oral secretions may lead to atelectasis of portions of the lung and further loss of respiratory function (4) Pulmonary edema which may occur when extensive bulbar disease is present. It brings about serious impairment of gas exchange in the lungs.

In estimating the condition of the respiratory muscles the appearance of the patient is extremely important. With mild degrees of respiratory muscle weakness the patient exhibits anxiety by facial expression restlessness irritability emotional lability and wakefulness. With more weakness of the respiratory muscles the face becomes flushed hypoxia and CO<sub>2</sub> retention increase pallor replaces the florid appearance there is inability to cough and respiration becomes rapid and labored with the use of accessory muscles. Certain clinical and laboratory procedures have proved of value in estimating the adequacy of the respiratory muscles. The strength of intercostal muscles is tested by having the patient expand the chest against manual pressure exerted against the lower portion of the rib cage. Intercostal muscles are also tested by restriction of the diaphragmatic excursion by manual force supplied to the upper part of the abdomen. As sniffing is brought about by descent of the diaphragm ability to carry out this action constitutes a test of diaphragmatic function. The resting small child with normal respiratory muscle function is able to hold its breath for fifteen to twenty seconds the child suffering from respiratory muscle impairment of relatively slight degree falls far short of this. Under certain circumstances a fluoroscopic examination to test diaphragmatic excursion is useful furthermore a spirometer should be used for accurate measurement of ventilatory exchange.

**RESPIRATORY AIDS** When only a small loss of function of respiratory muscles is present there is no need for mechanical aid to respiration. However when respira-

tory muscles are so impaired that conscious effort is necessary to supplement their action and thus compensation does not appear adequate then mechanical therapy is necessary. One of the factors indicative of respiratory inadequacy is the inability of the patient to obtain sleep. It is a mistake to wait for signs of hypoxia or CO<sub>2</sub> accumulation before using mechanical therapy for they represent signs of respiratory decompensation. In the use of mechanical aids to respiration the general principle is that the patient's possible needs must be anticipated and unexpected crises should be avoided. The patient's needs are best determined by following his vital capacity at regular intervals. A rapid fall in the vital capacity to levels below one fourth of the resting normal value almost always indicates the need for mechanical aids in ventilation. Every effort should be made to allay the patient's anxiety and emphasis should be placed upon the usually successful outcome. The apparatus to be used should be at hand and obviously members of the medical and nursing staff should be familiar with its operation.

For severe degrees of respiratory muscle weakness the *tank respirator* is the apparatus of choice. When relatively minor degrees of respiratory muscle weakness exist the cuirass respirator and the rocking bed may be employed to give rest and sleep. In general however both of these machines are of greatest use in the recovery period and in weaning patients from the tank respirator period. In the United States positive pressure devices seem to have been less well suited for prolonged use and are probably most valuable as an adjuvant for the tank respirator period. The main use of the *electrophrenic respirator* is in the treatment of respiratory impairment due to injury to the respiratory center.

For initiating the use of the tank respirator it should be appreciated that since respirator patients no longer control their respiratory rate they often attempt to breathe voluntarily and out of time with the bellows. By persistent instruction the patient is urged to relax and let the respirator do the work. In general younger children are given a more rapid respiratory rate than older children or adults but the rate should be determined by clinical observation in steering a course between underventilation as opposed to hyperventilation with excessive loss of CO<sub>2</sub> and alkalosis. Of the two hyperventilation is by far the lesser danger. Rates range from 30 per minute in young children to 18 per

minute in the adult. Younger children are subjected to smaller pressure ranges than adults although some competent and experienced physicians do not follow this practice. For small children an *intra tank* pressure starting at 0 and reaching -12 cm of water at its peak is suggested for the beginning. 0 to -15 for older children and 0 to -18 for adults may be tried. Some workers employ pressures which range from a positive reading of +3 or +4 to -18. The tidal exchange produced by each cycle of the respirator should be determined with a spirometer. The respirator should then be set at a rate and pressures which assure a minute volume of respiration as close to the resting normal as possible. In adults this is usually 6000 to 8000 ml. A decrease in tidal air and minute volume with constant *intra tank* pressures is often a valuable indicator of early interference with respiratory exchange in the lungs which is usually associated with obstruction of the bronchial tree. Signs of improvement which indicate successful action of a respirator include improvement or disappearance in the signs of anoxia such as restlessness, pallor or cyanosis, acceptance of the rhythm of the respirator and cessation of voluntary respiratory movements with relaxation so that the patient may fall asleep.

It should be appreciated that when respiratory difficulty is due entirely to weakness of the respiratory muscles the tank respirator is of great benefit. When improvement is not quickly obtained complicating factors must be sought. These include obstruction of the airway, pulmonary atelectasis, pneumonia or pulmonary edema.

Nursing care required by the patient in the tank respirator is of a special type. The patient's skin must be cared for, fluid, mineral and nutritional requirements must be met. Excessive handling of painful extremities should be avoided although the patient's position should be changed if possible every two hours. Physical therapy should be postponed until the patient has become well adjusted to the respirator. Infections of the upper respiratory passages—bronchitis and pneumonia—are serious and must be treated promptly. When pneumonia is present oxygen therapy is of value. Atelectasis is also a serious complication. Danger of its occurrence may be minimized by frequently changing the patient's position by obtaining maximum safe pulmonary ventilation by prevention of aspiration of secretions. When atelectasis

of any considerable degree occurs bronchoscopic drainage is usually necessary. In the event of pulmonary edema oxygen therapy should be given. When cardiac insufficiency is present digitalis and other measures to improve cardiac function are indicated. If the difficulty is caused by injury of the medullary respiratory centers such patients nearly always require mechanical aids to respiration. If the tank respirator fails the electrophrenic respirator may be used but certain difficulties in its use limit its value.

Obstruction of the airway resulting from an inability to swallow may induce respiratory difficulties. Not only does it interpose a barrier to the air entering the larynx and trachea but during inspiration the pooled secretions may be drawn into the trachea and bronchi. The general principle of treatment is to provide a free airway by postural drainage and mechanical aspiration of the secretions in the pharynx. This should be done if possible without trauma. If this fails tracheotomy is performed providing an airway which cannot be obstructed. A cooperative patient is less likely to require tracheotomy than a panic stricken one. Adults and older children are less likely to need it than very young children. Mechanical respiration is of no value in the treatment of respiratory tract obstruction.

Differing views exist as to the indications for tracheotomy and there are no dogmatic rules. It perhaps goes without saying that it should be performed if possible by one expert in the technique and not as a hurried last resort type of procedure.

It is wiser to operate when there is doubt as to the advisability of further watchful waiting even though occasionally the subsequent course of the patient may prove that survival without tracheotomy would have followed. A careful unhurried tracheotomy is neither mutilating nor dangerous.

The particular type of anesthesia selected depends upon the emotional state of the patient. In exceedingly frightened, panicky adults and in children general anesthesia is desirable. An endotracheal tube is passed and cyclopropane in high oxygen concentration is introduced via the tube. Cyclopropane accords rapid induction and rapid release from anesthesia. Local anesthesia is adequate in the more controlled adult. During local anesthesia artificial respiration is maintained by the anesthesia machine through a pharyngeal airway using 100 per cent oxygen. In either case artificial respiration with the anesthesia machine through the tracheotomy is continued as

the patient is returned from the operating room

The tracheotomy should be performed as high as possible i.e. just below the first tracheal ring so that the tube will be outside the respirator

For the first twenty-four to forty-eight hours after operation the patient is given nothing by mouth. Fluid and electrolyte balance is maintained by intravenous administration. At the end of forty-eight hours feedings of a soft diet are carefully given by an attendant and over the next several days solid foods are slowly introduced.

**MANAGEMENT IN RESPIRATOR** Once the tracheotomy is done a free airway can be maintained by repeated suctioning. In general the patient is placed in the tank respirator postoperatively. If the patient is able to maintain adequate respiration unaided he may be placed on the respirator bed with the respirator tank open and the bellows not operating. In this situation artificial respiration may be instituted at a moment's notice.

The respirator must be provided with an adjustable collar bar so that the tracheotomy is outside the respirator at all times.

The next most important task is to maintain a clear airway. First the physician must consider the tube itself. The tracheotomy tube should be changed forty-eight hours after initial installation and weekly thereafter. Second there should be ample opportunity for secretions to drain from both sides of the lungs. This is accomplished by placing the patient in the Trendelenburg position every one to two hours for about twenty minutes and by turning him from side to side every two hours. Intermittently he should be given a period on his back. In the case of severe respiratory involvement the periods of Trendelenburg position may need to be lengthened. Suctioning should be at frequent enough intervals to keep the airways free from secretions at all times. The immediate post-operative period may require nearly constant suctioning.

**Weaning** from the tank respirator should be instituted as early as possible when the patient is afebrile and as soon as he is able to do without the respirator for thirty to sixty seconds. The tank respirator is gradually replaced by a simpler device i.e. a cuirass respirator or a rocking bed.

**Early Convalescent Care** The aim in convalescent care is to restore the maximal functional capacity which is possible within the limits imposed by the actual damage to

the nervous system. It should be done with an awareness of the psychological impact on the patient which not only the illness but the therapy may have produced. During the period of after-care and rehabilitation favorable conditions should be provided for the restoration of normal function and the preservation of the limbs in the best condition for late orthopedic operations if such become necessary. Rehabilitation today calls for more than the care of limbs and should be directed from the start by physicians, orthopedists and technicians.

**Prevention** Vaccination against poliomyelitis is now an accepted procedure widely recommended. The effective use of the Salk type formalinized vaccine has changed the picture of the control of poliomyelitis in a number of countries in which it has been widely used and particularly in the United States where vaccination of all persons within the ages of one year to forty or forty-five years has been considered to be indicated. In using this prophylactic measure one should recall that the Salk type vaccine does not prevent infection with poliovirus (i.e. inapparent or asymptomatic infection) but it does materially reduce the spread of poliovirus within the bodies of those who become infected. In this fashion it lowers the incidence of paralytic poliomyelitis.

Current techniques for the administration of Salk type vaccine call for its intramuscular inoculation in three divided doses of 1.0 ml each the second being given one month to six weeks after the first and the third not earlier than seven to nine months after the second. There is as yet no universal agreement as to whether one or more "booster" inoculations are desirable at intervals of a year after the last dose. One indication for such inoculations is that the vaccinee expects to go to areas where the degree of exposure to polioviruses may be high such as the Middle East.

There is little or no evidence that the Salk type vaccine acts as a provoking agent which might induce paralytic poliomyelitis for irritating, allergic and other types of side reactions to the vaccine are uncommon and the contraindications to its use are few. Young children with severe eczema are one group which might be omitted from vaccination programs.

The decision to vaccinate individuals or a whole population during an epidemic or in the face of increased risk of exposure due to an advancing epidemic has both proponents and opponents. In general opinions support the view that such "pre-

minute in the adult Younger children are subjected to smaller pressure ranges than adults although some competent and experienced physicians do not follow this practice For small children an *intra tan* pressure starting at 0 and reaching -12 cm of water at its peak is suggested for the beginning 0 to -15 for older children and 0 to -18 for adults may be tried Some workers employ pressures which range from a positive reading of +3 or +4 to -18 The tidal exchange produced by each cycle of the respirator should be determined with a spirometer The respirator should then be set at a rate and pressures which assure a minute volume of respiration as close to the resting normal as possible In adults this is usually 6000 to 8000 ml A decrease in tidal air and minute volume with constant *intra tank* pressures is often a valuable indicator of early interference with respiratory exchange in the lungs which is usually associated with obstruction of the bronchial tree Signs of improvement which indicate successful action of a respirator include improvement or disappearance in the signs of anoxia such as restlessness pallor or cyanosis acceptance of the rhythm of the respirator and cessation of voluntary respiratory movements with relaxation so that the patient may fall asleep

ber and variety of symptoms. Most common is either a somnolent-ophthalmoplegic syndrome or an irritative hyperkinetic syndrome which may be choreiform or myoclonic. Psychic disturbances may occur with symptoms ranging from mental impairment to those of the major psychoses. Paralysis may develop and simulate poliomyelitis. There is a fulminating type in which the patient may succumb within a few hours. The fever may be slight or severe. Many afebrile cases have been noted. Inapparent disease occurs and may lead to the appearance of parkinsonism.

In the second or pseudopsychoneurotic stage there are many subjective complaints often without demonstrable objective findings of organic nervous disease. Headache, insomnia, dizziness, fatigability, irritability, and restlessness are common. Such symptoms may persist for months or years after which the symptoms of the third stage appear. Occasionally the third stage follows almost immediately upon the first.

In the third or chronic stage peculiar motor, vegetative, and psychic symptoms make their appearance. The disturbances of motility are like those of the Parkinson syndrome with or without tremor. Among the more common vegetative disturbances are sialorrhea, dacryorrhea, and seborrhea. There may be intellectual and emotional torpor.

**Diagnosis.** The diagnosis is difficult and the disease must be differentiated from the numerous encephalitides of established cause. When the disease is epidemic and typical cases are occurring, encephalitis lethargica may be suspected in puzzling cases of fever, somnolence, or delirium. There are no laboratory procedures available which are helpful in confirming the diagnosis.

**Prognosis.** The case mortality rate varied in past epidemics but may have been as high as 20 to 30 per cent. Among patients who survive a large number recover rapidly; others are partially disabled for six months to two years; still others are permanently disabled because of the severe symptoms of the third stage.

**Treatment.** Symptomatic and careful supportive treatment is all that is available. In spite of claims to the contrary, there is no evidence that any of the vaccines or serums used in treatment are of value.

## St. Louis Encephalitis

**Definition.** St. Louis encephalitis is a viral disease characterized by signs and symptoms referable to the central nervous system and its meninges. It may occur either epidemically or sporadically.

**History.** In the summer of 1933 in and around St. Louis more than 1000 cases of encephalitis occurred. Muckenfuss, Armstrong, and McCordock and Webster and Fite demonstrated that the epidemic was caused by a virus previously unrecognized. The malady is now endemic in America, cases having been reported each year since 1933.

**Epidemiology.** This disease is one of the many arthropod borne virus encephalitides. Certain species of mosquitoes have been shown capable of transmitting the infection. The malady occurs most frequently during the summer and fall months. No age is exempt but the highest incidence is in persons from fifteen to fifty years of age.

**Etiology.** The disease is caused by a small virus with dimensions of 20 to 30  $\mu$ . The virus is a member of the B group of arthropod borne viruses and is closely related to Japanese B, Murray Valley, West Nile, and certain others. It is also related to viruses of the Russian tick borne encephalitis complex which includes so called *Russian spring summer* or *Far East encephalitis*. The agent has been propagated in media containing viable susceptible cells. Mice and rhesus monkeys are susceptible hosts; the former is the one of choice for the demonstration of virus in suspected material and for the performance of neutralization tests used in arriving at a diagnosis.

**Incubation.** It has been estimated that incubation periods range from four to twenty-one days.

**Morbid Anatomy.** Edema, vascular congestion, and small hemorrhages are evident upon gross examination of the brain and cord. Microscopic examination reveals an infiltration of the meninges with lymphocytes, plasma cells, large mononuclear elements, and an occasional polymorphonuclear cell. In the brain and cord are evidences of an acute inflammation, e.g.,

epidemic" vaccination is indicated if the evidence of imminent heavy exposure is adequate

**General Procedures** During epidemics it is well to seek the counsel of the local health officer so that a uniform plan for diagnosis and handling of patients may be adopted

Although the isolation of patients as usually practiced has not proved to be effective in controlling the spread of the disease it is reasonable to regard acute poliomyelitis patients as infectious for a period of ten to twenty days following onset Therefore early recognition isolation and reporting of cases are all important The period of isolation of a patient with poliomyelitis ranges from one to three weeks from onset depending on local rulings Mention has already been made of techniques to be followed in disposing of feces

**Quarantine** of an exposed family or intimate group of contacts although not of proved value seems wise particularly in the form of modified quarantine which calls for the restriction of familial juvenile contacts for seven to fourteen days

For *passive immunization* in unvaccinated individuals subjected to heavy exposure concentrated immune globulin (gamma globulin) may be administered in a dosage of 0.1 ml per pound of body weight

Certain measures have been found useful during epidemics These are (1) the isolation in bed of all children with fever pending diagnosis (2) the education in such techniques of bedside nursing as will prevent distribution of infectious discharges to others from patients isolated at home (3) the protection of children as far as practicable against unnecessary contacts with other persons and the avoidance of unnecessary travel and visiting especially of children during the high prevalence of the infection (4) postponement of elective nose and throat operations dental extractions or other types of induced trauma of appreciable extent

## Encephalitis Lethargica

(Von Economo's Disease Epidemic Encephalitis)

**Definition** Encephalitis lethargica is a malady which causes both degenerative and inflammatory changes in the central nervous system and is characterized by diversity of symptoms in different cases and in successive stages of the same case It is unfortunate that the name epidemic encephalitis has been used other types of encephalitis occur in epidemic form and encephalitis lethargica now occurs only sporadically

**History** The disease became known after a pandemic broke out in the winter of 1916-1917 Von Economo carefully described the disease at that time and called it 'lethargic encephalitis' The first cases were seen in Rumania in 1915 Thereafter epidemics of the illness occurred in many parts of the world In 1918 it appeared in the United States After 1926 no further epidemics developed If the disease still occurs it is represented only by occasional sporadic cases

**Etiology** The cause of encephalitis lethargica is not known but there are reasons for thinking that the etiological agent may be a virus

**Morbid Anatomy** Hyperemia and minute hemorrhages may be present in the basal ganglia midbrain and pons Microscopically the lesions are of two sorts one degenerative the other inflammatory and infiltrative The degenerative process is characterized by destruction of nerve cells the inflammatory process by perivascular cuffing scattered patches of glial cell proliferation and lymphocytic infiltration Demyelination is not a prominent feature Lesions in the spinal cord are not marked

**Symptoms** The onset may be sudden or gradual Almost any type of neurological syndrome may be simulated there is a wide diversity of signs and symptoms The symptom-complex may be divided into three stages

In the first stage there are a large num

ceiving the injections met with "paralytic accidents" which at times resulted in death. In 1907 Comby described a case with involvement of the central nervous system as a complication of Jennerian prophylaxis. Although isolated cases had been described from time to time it was not until the outbreak of postvaccinal encephalitis in England, Holland and other countries in 1922 that attention was focused on them. As the result of extended clinical pathological and experimental observations the tendency is to consider this type of nervous accident following in the wake of acute infections as a clinical entity.

**Epidemiology.** The disease has been shown to occur during the course of and after vaccination against rabies and smallpox and after measles, German measles, varicella, mumps or influenza; a few cases have been reported in which no history of a preceding infection was obtained. The incidence varies from year to year, being lower now after Jennerian prophylaxis than it was in 1922-1925. It is not distributed uniformly throughout the population of a country, nor are the inhabitants of all countries equally affected. No age is exempt; the malady occurs, however, more frequently in children than in infants and adults. There is no evidence that the disease is contagious.

**Etiology.** The cause of postinfection encephalitis is not known; nor has the malady been transmitted from man to experimental animals. Three prevalent ideas regarding the etiology are: (a) the viruses that cause the primary disease, e.g., smallpox, measles, and so forth, also give rise to the complicating encephalitis; (b) a latent neurotropic virus is activated by the primary disease process; (c) inasmuch as the encephalitis occurs during convalescence from some infectious malady or after vaccination, certain workers have suggested that it is an expression of allergic phenomena. There is no convincing evidence that any of these ideas is correct. It seems unlikely, however, that the direct action of a virus is the cause of the disease, because no virus is known to produce a perivascular demyelination similar to that seen in this disease. Furthermore, Rivers and his co-workers, by means of repeated intramuscular injections of emulsions of fresh normal rabbit brain, have produced a perivascular demyelination in monkeys manifest clinically by ataxia and paralysis. This work has been confirmed and expanded.

**Incubation.** In view of the indecision regarding the etiology, it may seem inappropriate to speak of an incubation period. Regardless of the cause of the encephalitis

there is a definite relation between it and the primary infections. In postvaccinal encephalitis the "incubation" period in most instances lies between the ninth and thirteenth days. In antirabic vaccination the encephalitis or myelitis usually comes during the second half of the Pasteur treatment or after it has been completed. In measles the "incubation" period is not constant, but as a general rule the encephalitis follows the appearance of the rash at variable intervals—usually it comes after the defervescence, and at times the patient may have fully recovered from measles.

**Morbid Anatomy.** Pathological changes are found in both the white and gray matter of the brain and cord and are characterized by a minimal involvement of nerve cells and a perivascular infiltration or accumulation of cells accompanied by a destruction of myelin. The perivascular collections of cells consist largely of altered glial elements, many of which become phagocytic and take up large amounts of fat and degenerated myelin. This pathological picture is decidedly unlike that seen in the encephalitides caused by viruses, in many respects it is similar to that seen in acute multiple sclerosis and allied conditions.

**Symptoms.** There are two main types of the disease, the encephalitic and the myelitic; the former is more common in postvaccinal encephalitis, the latter during antirabic vaccination, while both types occur with almost equal frequency after smallpox. Under such conditions it is to be expected that the clinical picture will vary and that the form it takes will depend on whether the brain or cord is predominantly involved.

The onset of the disease, if not abrupt, is rarely insidious and is manifested in the encephalitic cases by pyrexia, headache, vomiting and drowsiness—cardinal symptoms constantly present in severe and rarely absent in mild cases; they may be the only symptoms present even in fatal cases. Photophobia, irritability, delirium, general or local convulsions, trismus, strabismus, incontinence of urine, extensive paralysis (spastic at first and then flaccid) or transient weakness of muscles, incoordination and ataxia are symptoms that may occur. Kernig's sign may be present; the deep and superficial reflexes are variable. In the myelitic cases symptoms caused by mild or severe involvement of the cord, such as paralysis, anesthetics, paresthesias and disturbances of sphincter control, are observed.

The cerebrospinal fluid may be under an

vascular congestion small hemorrhages cellular infiltration perivascular cuffing degeneration of nerve cells neuronophagia and proliferation of glial elements

**Symptoms** The fact that the clinical picture varies tremendously can be explained upon the basis of differences in the severity of the infection and the localization of lesions in the brain and cord. The clinical picture may resemble that seen in western equine Japanese B or Russian spring summer encephalitis. According to Hempelmann the cases may be placed in three large groups.

**Group I** Patients exhibit an abrupt onset without prodromal symptoms. High fever nausea vomiting headache vertigo nuchal rigidity Kernig's sign lethargy difficulty with speech ataxia mental confusion and tremor of tongue lips or hands are the most common signs and symptoms. Not all patients are lethargic paralyzes are not common and when they do occur are usually of the spastic type. Involvement of the eye muscles is extremely rare. The abdominal reflexes are usually absent while the deep reflexes tend to be exaggerated instead of diminished. Constipation is common. The pulse is usually proportional to the temperature but bradycardia may occur.

The cerebrospinal fluid may be under increased pressure is free from bacteria and contains a normal amount of sugar an increased amount of globulin and an increased number of cells consisting chiefly of lymphocytes and other mononuclear elements. The leukocyte count may be normal or show a moderate increase.

As the patient's condition improves the temperature falls by lysis and in most instances reaches the normal level within seven to ten days in a few cases however the fever persists for four to six weeks.

**Group II** In this group a stage of invasion lasting from one to four days and characterized by headache general malaise abdominal pains chilly sensations fever generalized muscular pains sore throat and mild conjunctivitis accompanied by photophobia precedes the picture of encephalitis which after its development is similar to that described for Group I.

**Group III** The third group consists of mild or abortive cases exhibiting only headache and fever of undetermined cause which would be missed in the absence of an epidemic and incorrectly diagnosed without the aid of a lumbar puncture.

**Diagnosis** Clinical or pathological observations may lead to a diagnosis of encephalitis but usually do not serve to distinguish

one type of viral encephalitis from another. A specific etiological diagnosis may be made by laboratory procedures. With specimens of serum taken during the acute phase and during convalescence neutralization hemagglutination inhibition and complement fixation tests may be of great aid in reaching a correct diagnosis.

**Prognosis** From 5 to 30 per cent of patients die the mortality rate is reported to increase directly with age. Those who recover do so quickly as a rule and are not usually bothered by troublesome or disastrous sequelae.

**Treatment** Treatment is symptomatic. No antimicrobial drugs have been shown to be effective.

## Postinfection Encephalitis

(Acute Demyelinating Encephalitis Acute Disseminated Encephalitis Postvaccinal Encephalitis Postmeasles Encephalitis)

**Definition** Postinfection encephalitis is an acute malady of the central nervous system characterized by perivascular demyelination exhibiting itself as a rule in patients convalescing from infectious diseases particularly those caused by viruses or in those who are being vaccinated against viral maladies such as smallpox or rabies. In certain instances the disease manifests itself in the absence of a history of preceding infection.

**History** An involvement of the central nervous system may complicate the picture of smallpox and measles. In 1874 Westphal recorded descriptions of pathological changes observed in the cords of patients who had died with nervous manifestations developing during an attack of smallpox and in 1886 Barlow and Penrose gave an account of a similar case that arose during the course of measles. Soon after the initiation of vaccination against rabies it was realized that an occasional patient re-

virus from a pigeon in similar circumstances. These findings implicate birds in the epidemiology of the disease and explain its spread to widely separated areas. Indeed it appears likely that the malady is primarily a disease of birds and that man and horses are accidental secondary hosts. The studies of Kissling and his associates have greatly extended our knowledge of the role played by birds and mosquitoes in the epidemiology of the disease.

**Prevention** Shahan and Giltner showed that a vaccine could be prepared by treating an emulsion of infective horse brain with formalin. Although some evidence of protection was obtained with this preparation the results were not entirely satisfactory. In 1935 Higbie and Howitt showed that the developing chick embryo could be infected with this virus. In 1938 Beard Finkelstein Sealy and Wyckoff prepared a vaccine by formalinizing a suspension of infected chick embryo tissue. Such tissues were found to contain a much higher content of virus than infective horse brain. This material has been widely used. Vaccination of horses and mules is achieved by subcutaneous injection at weekly intervals of two doses of 10 ml each of the vaccine of triturated chick embryo tissue treated with 0.4 per cent formalin. Experimental and field studies have shown that this method is very effective. Practical sanitary measures should of course be used such as screening stables and removing horses and mules from pastures after dark.

#### THE DISEASE IN MAN

Meyer in 1932 described three cases of encephalitis in persons having contact with sick horses which he suspected might be due to the virus of the equine disease. No proof for this suspicion was obtained however by biological test.

During the summer of 1938 an epidemic of the eastern variety of the disease occurred among horses in southeastern Massachusetts. During this time and in the same area an unexpected number of human cases of encephalitis occurred. These were proved by Fothergill Dingle Farber and Connerley and by Webster and Wright to be caused by the equine virus by isolating the infectious agent from the brain tissue of fatal cases.

There were about 40 human cases in this outbreak with a mortality of 65 per cent. The majority of cases occurred in young children 70 per cent of them less than ten years of age. During the summer of 1941

more than 3000 cases of the western type occurred in the north central states.

**Clinical Manifestations** The onset of the disease was usually sudden particularly in young children. The temperature rose rapidly to 103° to 105° F and generally remained at a high level during the course of the disease. In some cases the disease was ushered in by a convulsion. Repeated convulsions occurred during the course of the illness in many patients. Deep coma occurred rapidly and persisted throughout the acute stage. Nuchal rigidity stiffness of the back and positive Kernig's sign were usually present. Many of the younger patients exhibited a peculiar edema about the face and upper extremities. In some of the older patients the onset was more gradual.

**Laboratory Findings** Certain laboratory findings were of importance particularly during the first few days of illness. A leukocytosis was always present. The cerebrospinal fluid was under increased pressure and contained an increased amount of protein and a normal content of sugar. The cell count varied from 200 to 2000 per cu mm. Of considerable importance was the fact that from 60 to 90 per cent of the cells were polymorphonuclear leukocytes.

In fatal cases death occurred at variable times during the course of the disease most commonly during the first few days. In the few patients who recovered the acute phase of the illness terminated by lysis six to ten days after the onset. The majority of the patients who survived were left with severe mental and physical damage.

The western type of the disease is much less severe the mortality varying from 15 to 25 per cent. In fact serological surveys reveal many cases of subclinical infection.

**Diagnosis** It must be emphasized that a diagnosis of encephalitis in man due to the virus of equine encephalomyelitis cannot be made on the basis of the clinical findings. It may be confused with other types of acute infectious encephalitis such as poliomyelitis and St. Louis encephalitis. An increase in the incidence of encephalitis in man in an area where an epidemic of the disease is in progress in horses and mules should lead one strongly to suspect the equine type of the disease. Virus was not isolated from any of the Massachusetts cases by inoculation of animals with blood or cerebrospinal fluid.

A diagnosis can eventually be established in the majority of cases by certain biological tests. The most important of these is the isolation of the virus from the brain tissue

creased pressure is sterile and may contain an increased number of cells which are usually mononuclear elements the amount of sugar is within normal limits

**Diagnosis** The clinical picture of post infection encephalitis is at times not unlike that caused by certain known viruses for example St Louis encephalitis virus. Consequently it is important to remember that not all cases of encephalitis occurring in the wake of infectious diseases are necessarily postinfection encephalitis. In certain instances they undoubtedly represent other types for example some cases of encephalitis following antirabic vaccination are in reality rabies and some that occur after measles are of the hemorrhagic rather than the demyelinating type. Often it is difficult and at times impossible by means of clinical observations alone to differentiate post infection encephalitis from the other types. In view of this fact a history of an encephalitis during convalescence from a virus malady usually results in a diagnosis of postinfection encephalitis. As a rule such a diagnosis is correct but not always. At present a definite diagnosis of postinfection encephalitis can be arrived at only by a careful examination of the brain and cord which should show a characteristic perivascular demyelination.

**Prognosis** Ten to 50 per cent of the patients die the mortality rate is much higher in postvaccinal encephalitis (50 per cent) than it is in postmeasles encephalitis (10 per cent) the rate also varies from year to year being considerably lower now in postvaccinal encephalitis than it was in 1922-1925. The patients who recover usually do so completely sequelae occasionally occur and seem to be more frequent in cases developing after measles than in those following jennertian prophylaxis.

**Treatment** The treatment is symptomatic. Headache may be relieved by repeated lumbar punctures and the intravenous administration of hypertonic glucose solution.

## Equine Encephalomyelitis

### THE DISEASE IN HORSES

Equine encephalomyelitis has undoubtedly been present among horses and mules in this country for many years but was diagnosed as botulism, forage poisoning and similar illnesses. In 1931 it was proved to be caused by a filterable virus by Meyer Haring and Howitt during the course of their studies of an epidemic in the San Joaquin Valley in California. Since then our knowledge of its extent, epidemiology, transmission and prevention has accumulated rapidly.

In 1933 an epidemic occurred along the seacoast of Virginia and New Jersey and was shown by Ten Broeck and Merrill to be due to a virus immunologically distinct from that causing the disease in the West. The eastern disease moreover is more severe than the western with a considerably higher mortality rate (about 90 per cent as compared to 25 to 30 per cent). The two diseases are referred to as the eastern and western types of equine encephalomyelitis.

**Epidemiology** The first important clue to the mechanism of spread of epidemics was provided by Kelsers experiments in which he demonstrated that the virus could be transmitted by the mosquito *Aedes aegypti*. Subsequently Kelsers as well as other investigators showed that other mosquitoes including *A. sollicitans*, *A. cantator*, *A. texans*, *A. taeniorhynchus*, *A. dorsalis*, *A. nigromaculis* and *A. albopictus* may transmit the virus. It is of interest that the *Anopheles* mosquitoes fail to transmit the virus. Recent experiments have demonstrated transmission of the virus by *Culex tarsalis*. The mosquito transmission of the virus accounts for the spread of the disease in a particular area however it does not explain the sudden appearance of the malady in widely separated areas.

Giltner and Shahan showed that pigeons were susceptible to infection after intra-cerebral inoculation of the virus and suggested that birds may play a role in the epizootiology of the disease. Other investigators demonstrated that other species of birds are also susceptible. During the course of the 1938 epidemic in Massachusetts Tyzzer, Sellards and Bennett isolated the virus from pheasants dying in their natural state and Fothergill and Dingle isolated the

## VIRAL DISEASES (PRESUMPTIVE)

### Epidemic Hemorrhagic Fever

(Manchurian Fever)

**Definition** Epidemic hemorrhagic fever is an acute disease of unknown etiology which occurs during the spring and fall in northeastern Asia. It is characterized by fever, prostration, vomiting, proteinuria, hemorrhagic manifestations (shock and renal failure).

**History** Beginning in 1951 seasonal outbreaks of a disease previously unknown to Western medicine occurred among the UN troops in Korea. It was soon learned that the Japanese had encountered an identical clinical entity in eastern Manchuria which they named epidemic hemorrhagic fever. This disease was apparently first described in Far Eastern Siberia under the name hemorrhagic nephroses by the Russians in the mid 1930's.

**Etiology** Russian investigators reproduced the disease in human volunteers by the parenteral injection of serum or urine obtained prior to the fifth day of illness from patients with the naturally occurring disease. They further found that the disease agent was filterable through a Berkefeld filter (grade N) that the incubation period was usually twelve to sixteen days and that a single attack conferred immunity. Extensive efforts to grow the causative agent on media and tissue cultures were failures as were efforts to establish the disease in a variety of lower animal hosts.

**Epidemiology and Mode of Transmission** Hemorrhagic fever has been contracted only in northeastern Asia including Korea north of Seoul and perhaps in central Russia. Sporadic cases occur throughout the year but large outbreaks in the late spring and fall account for the majority of attacks. All ages, sexes and races are susceptible. The disease occurs only in rural areas and most cases occur as isolated events widely separated in time and place even during epidemics. Person to person transmission does not occur. Inability to isolate the causative agent has precluded definitive demonstration of the mode of transmission of epidemic hemorrhagic fever. However, its epidemiology is reminiscent of that of scrub

typhus and careful studies strongly incriminate one or more species of trombiculid mites which infest certain field rodents.

**Morbid Anatomy** Profound protein rich retroperitoneal edema is characteristic of early deaths in shock but not of later deaths. Certain viscera are also edematous although dehydration of most regions is the rule. The kidneys are swollen and exhibit extreme congestion sharply localized to the medulla while the right atrium appears hemorrhagic and the anterior pituitary exhibits congestion or hemorrhagic necrosis. Similar congestion or hemorrhage may occur in the stomach, adrenals, lungs and central nervous system. These areas derive their appearance from extremely dilated and congested small blood vessels especially in the renal medulla. Petechial hemorrhages may occur in the skin, heart, adrenals and brain.

**Clinical Course and Pathological Physiology** The clinical and laboratory manifestations of hemorrhagic fever make up a confusing array of problems that occur in rapid sequence with considerable overlapping and variation in severity. However, most patients follow a fairly typical course which is conveniently considered in relation to several phases. The course of important clinical and laboratory features of a moderately severe case is shown in Figures 13 and 14. Although all patients exhibit proteinuria and many have petechiae and some degree of hemoconcentration, hypotension and renal failure consequences such as shock, serious hemorrhages and fluid and electrolyte imbalances occur in no more than 20 per cent.

**The febrile phase** lasts three to eight days and is characterized by fever, malaise, a flush of the face and neck, injection of the eyes and palate and other nonspecific features. Evidence of widespread vascular dysfunction appears at this time. Toward the end of the febrile phase, petechiae occur, blood platelets decrease, the hematocrit begins to increase and faint traces of protein appear in the urine.

**The hypotensive phase** develops suddenly during defervescence and generally lasts one to three days. Despite shock which

of acute fatal cases obtained at necropsy. It is advisable to take small portions of brain tissue from various regions in the brain and brain stem. The tissue is emulsified in physiological salt solution and inoculated intracerebrally into white Swiss mice or guinea pigs. If virus is recovered it can be identified by immunological tests (protective tests in actively immunized animals or by serum neutralization tests). If it is impossible to inoculate animals immediately brain tissues can be preserved in the icebox in a mixture of 50 per cent neutral glycerin in buffered Tyrode solution. It is important to preserve such material in a buffered mixture since the virus is inactivated rapidly by the developing cadaveric acidity. Histological examination is of course of great value in diagnosis.

In cases with a prolonged illness and in convalescent patients a diagnosis may be made by neutralization tests with patients' serum. Neutralizing antibodies appear seven to ten days after the onset of the illness.

**Treatment.** There is no specific therapy for this disease. Treatment is entirely symptomatic, consisting in the administration of sedatives for the control of convulsions, administration of fluids parenterally and food by gavage during the period of coma.

**Prevention** of the disease in man if an epidemic occurs should consist largely in

sanitary measures. Houses and particularly sleeping quarters should be screened against mosquitoes and children should not be allowed outside after sundown. A vaccine has been used in persons under unusual risk such as laboratory workers. The infrequency of the disease in the latter does not justify large scale vaccination.

### Epidemic Hemorrhagic Fever

(Manchurian Fever)

**Definition:** Epidemic hemorrhagic fever is an acute disease of unknown etiology which occurs during the spring and fall in northeastern Asia. It is characterized by fever, prostration, vomiting, proteinuria, hemorrhagic manifestations, shock, and renal failure.

**History:** Beginning in 1951 seasonal outbreaks of a disease previously unknown to Western medicine occurred among the UN troops in Korea. It was soon learned that the Japanese had encountered an identical clinical entity in eastern Manchuria which they named epidemic hemorrhagic fever. This disease was apparently first described in Far Eastern Siberia under the name hemorrhagic nephros-nephritis by the Russians in the mid 1930's.

**Etiology:** Russian investigators reproduced the disease in human volunteers by the parenteral injection of serum or urine obtained prior to the fifth day of illness from patients with the naturally occurring disease. They further found that the disease agent was filterable through a Berkefeld filter (grade N) that the incubation period was usually twelve to sixteen days, and that a single attack conferred immunity. Extensive efforts to grow the causative agent on media and tissue cultures were failures as were efforts to establish the disease in a variety of lower animal hosts.

**Epidemiology and Mode of Transmission:** Hemorrhagic fever has been contracted only in northeastern Asia, including Korea north of Seoul and perhaps in central Russia. Sporadic cases occur throughout the year, but large outbreaks in the late spring and fall account for the majority of attacks. All ages, sexes, and races are susceptible. The disease occurs only in rural areas and most cases occur as isolated events, widely separated in time and place, even during epidemics. Person to person transmission does not occur. Inability to isolate the causative agent has precluded definitive demonstration of the mode of transmission of epidemic hemorrhagic fever. However, its epidemiology is reminiscent of that of scrub

typhus, and careful studies strongly incriminate one or more species of trombiculid mites which infest certain field rodents.

**Morbid Anatomy:** Profound protein rich retroperitoneal edema is characteristic of early deaths in shock, but not of later deaths. Certain viscera are also edematous, although dehydration of most regions is the rule. The kidneys are swollen and exhibit extreme congestion, sharply localized to the medulla, while the right atrium appears hemorrhagic and the anterior pituitary exhibits congestion or hemorrhagic necrosis. Similar congestion or hemorrhage may occur in the stomach, adrenals, lungs, and central nervous system. These areas derive their appearance from extremely dilated and congested small blood vessels, especially in the renal medulla. Petechial hemorrhages may occur in the skin, heart, adrenals, and brain.

**Clinical Course and Pathological Physiology:** The clinical and laboratory manifestations of hemorrhagic fever make up a confusing array of problems that occur in rapid sequence with considerable overlapping and variation in severity. However, most patients follow a fairly typical course which is conveniently considered in relation to several phases. The course of important clinical and laboratory features of a moderately severe case is shown in Figures 13 and 14. Although all patients exhibit proteinuria and many have petechiae and some degree of hemoconcentration, hypotension, and renal failure, consequences such as shock, serious hemorrhages, and fluid and electrolyte imbalances occur in no more than 20 per cent.

**The febrile phase** lasts three to eight days and is characterized by fever, malaise, a flush of the face and neck, injection of the eyes and palate, and other nonspecific features. Evidence of widespread vascular dysfunction appears at this time. Toward the end of the febrile phase, petechiae occur, blood platelets decrease, the hematocrit begins to increase, and faint traces of protein appear in the urine.

**The hypotensive phase** develops suddenly during defervescence and generally lasts one to three days. Despite shock, which

FIG 13 Hemorrhagic fever abnormal physiology

FIG 14 Severe hemorrhagic fever course of certain laboratory findings

accounts for a third of all deaths the extremities may remain warm and arterial dysfunction may contribute to the hypotension. The dominant feature however is a reduction in blood volume due to loss of plasma from the vascular system as evidenced by a rapid increase in hematocrit to as high as 70 per cent and to trapping of erythrocytes in dilated capillaries. Heavy proteinuria, oliguria, acute renal failure and hemorrhages of capillary origin associated with thrombocytopenia are prominent clinical features whether or not hypotension develops. Nausea and vomiting are common while backache and abdominal discomfort result from localized edemas.

The leukocytes which earlier were normal or reduced now show a leukemoid reaction.

The oliguric phase begins as the hematocrit decreases and the sequestered plasma returns to the vascular system. It usually lasts for three to five days. Deaths in this phase are due to pulmonary edema, electrolyte abnormalities and shock secondary to dehydration or pulmonary complications. This phase is one of increasing renal failure and nitrogen retention, continued vomiting and dehydration. Hyperkalemia is common. Despite improvement in many of the earlier symptoms, increasing confusion and extreme restlessness are common as is hypertension. Some patients exhibit a hyper-

*toleptic syndrome* which may respond to phlebotomy. Hemorrhages into the skin, sclerae, gastrointestinal tract, lungs, and renal pelvis continue but rarely are large in amount and generally decrease toward the end of the oliguric phase.

The *diuretic phase* which may last for days or weeks usually initiates clinical recovery and rapid improvement in renal function. However, a diuresis of 3 to 8 liters daily represents a hazard to patients who are already extremely dehydrated and who have had limited caloric intake for seven to ten days. These patients exhibit a brittle fluid volume homeostasis and may fluctuate rapidly between shock on the one hand and hypertension and pulmonary edema on the other depending on the state of the fluid balance. Serious potassium deficiency is not uncommon while hypernatremia can be troublesome. Deaths in this phase account for a third of the total and are usually due to shock secondary to dehydration and to pulmonary complications including bacterial infections. The diuresis characteristic of this phase does not represent mobilization of edema fluid but is the result of residual renal tubular damage.

*Convalescence* requires three to twelve weeks and is characterized by gradual return of appetite, strength and urinary concentrating ability to normal.

**Diagnosis** In the absence of any specific test the diagnosis must be made on clinical evidence and should be suspected when an acute febrile illness associated with the characteristic flush and petechiae occurs in a subject who has been in an endemic area. The subsequent developments such as hypotension or shock, increased hematocrit, thrombocytopenia, oliguria and renal failure assist in establishing the diagnosis but 3 to 4 plus proteinuria developing near the time of defervescence is the single most useful diagnostic sign.

**Prognosis** The case fatality rate among US Armed Forces once techniques for prompt diagnosis and early adequate treatment were developed has been 5 per cent or less. No single finding is of great prognostic value in individual patients. However, prolonged high fever, protracted or recurrent shock and persistent hemoconcentration are all ominous features. With rare exceptions, survivors who have not had central nervous system hemorrhages make apparently complete recoveries.

**Treatment** Since antimicrobial drugs, convalescent serum, hormones and other agents are entirely ineffective, the manage-

ment of hemorrhagic fever must be supportive and based on an understanding of its physiological and biochemical characteristics and on frequent clinical observations. Adequate sedation with barbiturates or opiates is frequently required for restlessness. Contrary to the practice in other febrile diseases, fluid intake must be limited since any excess will simply leak out of damaged capillaries and increase edema and symptoms. When intravenous fluid is required it usually should be 10 per cent dextrose in water and must be given very slowly. If shock fails to respond to simple measures such as shock blocks, then concentrated (salt poor) human serum albumin to restore plasma volume and continuous intravenous infusion of pressor drugs (preferably Arterenol) may be required. Doses of the latter must be based on the response of the shock, blood pressure and hematocrit. Occasionally large doses of both albumin and pressor drugs are required. Treatment in the oliguric phase is that of acute renal failure with careful control of electrolytes and particular attention paid to hyperkalemia. If oliguria persists for more than a few days, 20 to 50 per cent dextrose in water (600 to 800 ml per day) may be given by continuous intravenous drip through a polyethylene catheter placed in a great vein. Phlebotomy may be required for the fully developed hypervolemic syndrome. The chief problem of the diuretic phase is one of careful matching of fluid and electrolyte intake against the brisk urinary output so as to avoid excessive dehydration and shock on the one hand and hypervolemia and pulmonary edema on the other. Electrolyte abnormalities are still a problem, especially potassium deficiency.

**Prevention** Preventive measures are based on the assumption that the disease is transmitted by an arthropod parasite of a rodent. Control of the rodent population and individual measures such as dipping all clothing in miticide solution and use of insect repellents have been used by the Armed Forces in Korea. The effectiveness of such measures has not yet been established, although each outbreak of hemorrhagic fever in Korea has been smaller than the preceding epidemic.

## Infectious Mononucleosis

**Definition** Infectious mononucleosis is a disease of unknown etiology and of protean symptomatology occurring principally in the first three decades of life and characterized typically by lymphadenopathy lymphocytosis (largely due to abnormal lymphocytes) and an elevated titer of sheep cell agglutinins in the serum

**History** Emil Pfeiffer in 1889 is generally credited with having first called attention to the disease which he termed glandular fever West was the first to report the disease in the United States The increase in the small mononuclear elements in the blood was reported by Burns in 1909 Between 1909 and 1920 various reports were made of what appear to have been sporadic forms of the disease In 1920 the term infectious mononucleosis was proposed by Sprunt and Evans who also called attention to the presence of abnormal cells in the blood Downey and McKinlay made a detailed report of the hematological findings in 1923 Paul and Bunnell in 1932 were the first to call attention to the presence of sheep cell agglutinins in the serum in this disorder

**Incidence** Infectious mononucleosis is not limited to any one geographical location It has been reported in America Europe Egypt Australia China Japan and elsewhere It may occur in either the epidemic or the sporadic form although most reports have dealt with the latter type The disease may occur at any age cases having been reported at seven months and seventy years but the great preponderance of patients with the disease is found between the ages of ten and thirty five Until recently it has been thought that the incidence in Negroes was low However a number of cases of the disease in Negroes have been reported in the past few years Wechsler and his co-workers found that forty nine Negroes or 8.7 per cent of the total number of patients in a large epidemic were affected

**Etiology** Infectious mononucleosis presumably represents either a single infection or a common host reaction pattern to several infections for it may occur as a localized epidemic as well as in the form of

sporadic cases It is generally considered that a virus or filterable agent is responsible for the condition but as yet no definitive proof of this has been offered Transfer of the disease to monkeys by means of a filtrate of nasal washings has been reported but there has been failure to confirm this work During recent years a wide variety of inoculums have been used in sixty one individual attempts to transfer the disease to human volunteers Successful results have been claimed in only two instances Evans who is responsible for twenty one of the experiments in human beings had negative results as regards transmission of the disease in every instance He suggested that failure to transmit the disease might be due to extreme lability of the causative organism and/or to low individual susceptibility Whatever the answer may be the evidence at the present time does not justify any designation of the causative factor

**Morbid Anatomy** The morbid anatomy of infectious mononucleosis is much more clearly understood than previously as a result of postmortem studies on several patients who succumbed to the disease Gross changes are limited almost entirely to enlargement of the lymphoid tissue including the spleen Other gross features include frequent enlargement of the liver rare icterus and occasional skin lesions The histological lesions tend to be generalized and closely resemble those of some of the viral diseases They consist mainly of perivascular aggregates of normal and abnormal lymphocytes Most of the tissues with the exception of the bone marrow have been shown to have these lesions The lymphocytes are absent in the bone marrow sections whereas aspirated marrow specimens do contain them as a consequence of admixture with peripheral blood Recently granulomatous lesions have been demonstrated in the bone marrow The lymph nodes which contain large numbers of abnormal lymphocytes show varying pictures from follicular hyperplasia to changes simulating those of a malignant lymphoma Lymphocytic infiltration of the capsule and trabeculae of the spleen occurs regularly The trabeculae are often dissolved by these infiltrations resulting in rupture of the spleen in rare instances Perivascular accumulation of the lymphocytes about the arteries of the trabeculae is to be expected Moreover subintimal accumulation of these cells in the veins of the spleen is constantly found Pneumonic exudate of either the round cell or neutrophilic types may occur Small myocardial infiltrates are found fre-

quently. In addition periportal round cell accumulation in the liver and various lesions of the nervous system in particular meningo-encephalitis are often encountered.

**Symptoms** Infectious mononucleosis is protein in its manifestations. The classic or so-called "typical" case may be described as follows.

A young adult is typically affected probably five to fifteen days after exposure to the causative organism. Malaise with or without sore throat but with fever and lymphatic enlargement—more typically of the posterior cervical nodes but frequently of all the nodes—characterizes the onset. The fever is of no definite type but usually is not pronounced. It lasts ordinarily for five to ten days but variations from absence to persistence for several weeks may occur. The nodes which are moderate in size (usually not over 3 cm in diameter) discrete slightly indurated nonsuppurative and sometimes slightly tender generally return to normal size in three to four weeks. Slight splenomegaly occurs in approximately one third of the cases and ordinarily recedes at the same time as the lymphadenopathy. The duration of active clinical signs and or symptoms varies from a few days to a few weeks or more. Leukopenia is common in the first week of the disease followed by moderate leukocytosis in the second and third weeks. This leukocytosis is due to an increase in the number of lymphocytes many of which are abnormal. In general the leukocyte picture returns to normal gradually within three to four weeks. The sheep cell or heterophile agglutination test becomes positive usually within the first two weeks of the illness. The thymol turbidity test is said to be positive in as high a percentage of cases as the sheep cell agglutination test. Some of the other liver function tests have also shown abnormal findings. Serological tests for syphilis may be positive in 3 to 10 per cent of the cases. No other significant abnormal laboratory findings occur in the usual patient with this disease.

Toxic symptoms such as headache malaise generalized aching anorexia and so forth are present in the acute phase in many instances. Moreover exudative pharyngitis tonsillitis and gingivitis with or without Vincent's organism occur in an appreciable percentage of the cases.

Some of the many variations which may be found in this disease are worthy of special comment.

**Latent Forms** The disease occurs in an

appreciable number of persons in the absence of signs or symptoms the diagnosis being made by means of changes in the leukocyte picture and/or serological tests.

**Cutaneous Eruption** Skin eruptions of one type or another may occur. Wechsler and his associates reported dermatological lesions in 16 per cent of their patients but the incidence in other reports has varied from 4 to 100 per cent. The most common skin rashes are of the macular and/or maculopapular types. Other types such as morbilliform polymorphous nodular vesicular urticarial and hemorrhagic are found at times.

**Abdominal Types** Jaundice with or without hepatomegaly may occur in a small number of patients being found in 6 per cent (thirty four cases) of those composing the epidemic studied by Wechsler. Liver biopsies abnormal liver function tests and autopsy findings have indicated that hepatitis rather than obstruction of the common duct by enlarged lymph nodes is responsible for the jaundice. In very rare instances the hepatitis may be extreme. It must be emphasized however that there is no certain way to distinguish between hepatitis as a complication of mononucleosis and viral hepatitis. Hence in the absence of serological evidence of infectious mononucleosis it is advisable to manage the illness as if serum or infectious hepatitis were present.

**Abdominal pain** secondary to enlarged mesenteric nodes is not uncommon. Rarely appendiceal involvement and rupture of the spleen may occur. Thirteen cases of rupture of the spleen with five deaths have been reported.

**Cardiac Involvement** Focal myocarditis and electrocardiographic changes such as abnormal T waves and prolonged P R intervals are common. However clinical symptoms referable to the heart are conspicuously absent.

**Pulmonary Involvement** Clinical evidence of pulmonary involvement is rare. Wechsler and his colleagues have reported that 25 per cent of their cases showed pulmonary lesions similar to those of atypical pneumonia. Whether the pulmonary changes in these cases were due to infectious mononucleosis or to some secondary complicating infection is not established.

**Neurological Involvement** Symptoms indicative of involvement of the cerebral meninges the brain the cranial nerves the peripheral nerves the spinal roots and the spinal cord have been reported. Typical cases of the Guillain Barre syndrome have

occurred in two of these deaths resulted. Also cases of encephalomyelitis with a symptomatology suggesting poliomyelitis have been reported. Pleocytosis and changes in the protein content of the cerebrospinal fluid may occur. Seven patients with central nervous system involvement are known to have died as the result of neurological complications.

**Hematological Abnormalities.** Granulocytopenic leukopenia at the onset followed by lymphocytic leukocytosis constitutes the principal abnormality in the blood. In some instances polymorphonuclear leukocytosis precedes the lymphocytic leukocytosis and the granulocytic leukopenia. The leukopenia is usually supplanted by leukocytosis during the second week of illness owing to an increase in the number of lymphocytes many of which are abnormal. Downey's description of the three types of abnormal lymphocytes which may occur still remains one of the best. His Type I cell is characterized by heavy staining irregular or bean shaped nuclei without nucleoli and with dark blue foamy cytoplasm. His Type II cell is characterized by relatively large amounts of light blue cytoplasm and a relatively normal appearing eccentrically placed nucleus. His Type III cell occurs much less often than either Type I or Type II and is distinguished by its resemblance to malignant or leukemic cells. The lymphocytosis is of varying degrees and is both relative and absolute. The percentage of lymphocytes varies widely at times being above 90. Further the actual percentage of abnormal lymphocytes varies greatly from patient to patient. These abnormal cells are in no sense specific being found in a variety of clinical disorders particularly some of the viral infections. Epidemic or infectious hepatitis at times has a leukocyte picture indistinguishable from that found in infectious mononucleosis. A similar but less marked blood picture may be found at times in a number of acute illnesses of viral origin. Most of the lymphocytes are approximately the size of small or intermediate lymphocytes but there are usually a few cells much larger and with nuclei showing nucleoli.

In most patients the leukocyte picture is the only blood change of any significance. However a few cases with anemia and/or thrombocytopenia have been reported. Also hemolytic anemia may occur rarely. Agranulocytosis has been noted in only one instance. An increased erythrocyte sedimentation rate is found but of course is in no sense specific.

**Serological Findings.** The sheep cell or heterophile agglutination test constitutes one of the most important diagnostic procedures in this disease. Paul and Bunnell were the first to call attention to this fact. They assumed that the heterophile antibody of infectious mononucleosis was of the Forssman type but Bailey and Raffel and Stuart showed later that this antibody could be distinguished from that of serum sickness and from that of normal serum. Thus there may be at least three types of agglutinins for sheep cells in the serum of human beings. The agglutinins associated with serum sickness have been said to be completely adsorbed by either guinea pig kidney or beef erythrocytes those associated with normal serum to be almost completely adsorbed by guinea pig kidney but not by beef erythrocytes and those associated with infectious mononucleosis to be completely adsorbed by beef erythrocytes but not significantly by guinea pig cells. However Dempster has called attention recently to the fact that there are distinct exceptions even to these latter assumptions.

There has been considerable argument as to what constitutes a significant titer in infectious mononucleosis. This probably varies from laboratory to laboratory depending upon the technique used. Paul has suggested the following ranges for titers: 1:10 to 1:40 negative; 1:80 to 1:160 suspicious; above 1:160 positive. A rising titer is the best criterion in the early stages of the disease. The differential adsorption tests are of distinct advantage particularly when the titer is in the lower ranges. In rare instances Hodgkin's disease and leukemia may have very high titers which are completely abolished by adsorption with guinea pig kidney. Usually adsorption with guinea pig kidney is satisfactory but in some instances adsorption by both guinea pig kidney and beef erythrocytes is needed to clarify the diagnosis. The exact incidence of the positive sheep cell agglutination test in infectious mononucleosis is not established. Certainly all cases do not show the positive test. In Paul's series the test was positive for 20 to 40 per cent of the cases in the first week, for 60 per cent of the cases in the second week and for considerably fewer in the fourth week. In Dempster's series 66 per cent of the cases of infectious mononucleosis gave positive agglutinin adsorption reactions. Hemolysins for ox cells are often greatly elevated in infectious mononucleosis and appear to retain a diagnostic titer for a longer period than do sheep cell agglutinins. Titration of

these hemolysins may therefore have particular value at a time when the agglutinin titer may be suspected to have declined

As previously indicated the serological tests for syphilis are falsely positive for a small number of these patients possibly 3 to 10 per cent. Moreover cold agglutinins in significant titer and abnormal liver function tests have been reported

**Diagnosis** The diagnosis of infectious mononucleosis is not difficult in the typical case with lymphadenopathy, splenomegaly, lymphocytosis and positive sheep cell agglutination. All of these findings may be absent in certain stages of the disease however and one or more of them may be absent throughout the illness. Streptococcal sore throat, Vincent's angina and diphtheria may be confused with the oropharyngeal lesions. Infectious hepatitis and homologous serum jaundice may be mistaken for this disease and vice versa since the leukocyte picture may be identical in these disorders. Typhoid fever and undulant fever may be confused with the disease at times when leukopenia is present. The skin lesions may lead to confusion with typhus fever, rubella, secondary syphilis and scarlet fever. The neurological involvement may raise the question of a large number of neurological disorders such as lymphocytic choriomeningitis, encephalitis, Guillain-Barré disease and poliomyelitis. Leukemia, idiopathic thrombocytopenic purpura and infectious lymphocytosis may be simulated at times. Infectious lymphocytosis is differentiated by hyperleukocytosis, negative sheep cell agglutination test and the absence of atypical lymphocytes.

**Prognosis** In general the prognosis of infectious mononucleosis may be considered good. Most of those affected recover within three to six weeks without sequelae. However severe complications such as hepatitis, thrombocytopenia, myocarditis, spontaneous rupture of the spleen and involvement of the central and/or peripheral nervous system may occur. Several instances of fatal outcome from rupture of the spleen, involvement of the nervous system and myocarditis have been recorded. In rare instances the spleen and/or lymph nodes may remain enlarged for long periods of time. Neurological symptoms may persist for varying intervals. Neurological complications and rupture of the spleen account for most of the deaths (12 out of 16) from this disorder. Recurrences and relapses have been reported but the writer's experience is in conformity with that of Contratto to the

effect that they are generally absent in patients who have actually shown recovery.

**Treatment** There is no specific treatment for infectious mononucleosis. Sulfonamides, penicillin, chloramphenicol and the tetracyclines have been tried without evidence of benefit. Rest is indicated in the presence of acute symptoms. It is probably wise to limit activities considerably in any known case even when fever and acute symptoms are absent because of the danger of rupture of the spleen. When jaundice is present a high carbohydrate and protein diet in addition to limitation of activities is indicated. Palliative measures of various types depending upon the symptomatology in individual cases are indicated. In severely ill patients a prompt remission can usually be obtained by the use of corticotropin or cortisone but the advantages and disadvantages of such treatment have not yet been defined.

#### Cat Scratch Disease\*

(Cat Scratch Fever, Sterile Regional Lymphadenitis, Benign Lymphoreticulousis of Inoculation)

**Definition** Cat scratch disease is a benign subacute regional lymphadenitis which may proceed to sterile suppuration or subside spontaneously. An indolent primary skin lesion at the site of a cat scratch precedes the adenitis.

Appreciation is expressed to Dr Frank G Mac Murray for his assistance in the preparation of this section.

**History** About 1932 Foshay in Cincinnati differentiated the disease from tularemia and Debre in Paris independently recognized it as a specific entity. Hanger and Rose devised a specific intradermal test in 1945.

**Incidence** Since the description of cat scratch disease by Debre in 1950 hundreds of cases have been recognized throughout the world. It is a common disease and wherever physicians become informed of its manifestations many cases are found.

**Epidemiology** Most victims have cat contacts, the majority being scratched and a few bitten. Occasionally inoculation follows the prick of a thorn or splinter. Household epidemics center about the family cat. Suspected cats appear healthy and presumably transmit the disease passively. Children are affected more frequently than adults.

**Etiology** The causative agent has not been isolated. The disease has been transmitted to monkeys and to one human by intracutaneous inoculation of infected lymph node suspension. Granular corpuscles found in cells of nodes are considered by some to be a visible form of the "virus" and by others to be nonspecific. A minority of patients have a low titer of complement fixing antibodies to lygranum complement fixing (CF) antigen. The reaction, however, is also found in others, especially among older controls not affected with the disease and with no history of an attack. Complement fixing reactions to lygranum CF is thus without diagnostic value in the individual case and affords no convincing evidence that the disease belongs to the psittacosis lymphogranuloma group of diseases.

**Pathology** Histologically the lymph nodes have shown reticuloendothelial hyperplasia and later focal granulomas with necrotic centers surrounded by epithelioid cells. Langhans giant cells are common. The process frequently involves the pericapsular connective tissue.

**Clinical Manifestations** A few days following a cat scratch or other skin injury about half the patients develop an indolent primary skin lesion. This appears as a persistent infected scabbed ulcer or scratch or a papule surmounted by a vesicle or pustule. About one to three weeks later the regional lymph nodes become remarkably enlarged and fever and symptoms of infection usually develop. The nodes may be elastic, movable and virtually insensitive or fixed, red and tender. They may recede spontaneously in weeks to months or suppurate with the development of sterile pus.

Lymphangitis does not occur. The epitrochlear axillary and inguinal femoral forms are unilateral; the cervical form is frequently bilateral. Enlarged nodes may occur in unusual sites as under the edge of the pectoral or trapezius muscles. Infected thyroglossal cyst may be simulated.

Rarely the eye is the site of inoculation causing Parinaud's oculoglandular syndrome (unilateral conjunctivitis with enlargement of the homolateral preauricular lymph node). Encephalitis occasionally complicates the disease, recovery occurring without residuals. Macular or papular rashes and erythema nodosum are occasionally seen.

**Laboratory Findings** Intradermal Test: Aspirated pus is diluted 1:5 with isotonic sodium chloride solution and heated to 60°C for one hour on two consecutive days. When proved sterile, 0.1 ml is injected intracutaneously. At forty-eight hours a positive reaction is indicated by a papule 0.5 to 1.0 cm in diameter or an area of erythema 1.0 to 6.0 cm in diameter or both. A positive reaction is indicative of past or present infection. Negative reactions, however, have been obtained in a few patients who had illnesses clinically and often pathologically suggestive of cat scratch disease.

The leukocyte count is usually normal. The erythrocyte sedimentation rate is often rapid. Cultures of pus or removed nodes are sterile.

**Diagnosis** Cat scratch disease may simulate a wide variety of lymph node diseases such as tularemia, infectious mononucleosis, lymphosarcoma, Hodgkin's disease, tuberculous adenitis, pyogenic adenitis, subcutaneous abscesses, lymphogranuloma venereum and both benign and malignant tumors. Appropriate examinations to exclude other diseases and the intradermal test with cat scratch disease antigen will lead to the proper diagnosis. In the presence of a typical clinical history, pathological findings consistent with this disease and a positive intradermal test, an unequivocal diagnosis can be made. Whenever there is doubt as to the etiology of a lymph node disease, an intradermal test with cat scratch antigen may avoid the necessity of biopsy and release the patient and physician from the fear of some more serious ailment.

**Prognosis** This is a benign self-limited disease which may last from two weeks to two years.

**Treatment** Chloramphenicol or the tetracyclines may shorten the course of the disease and prevent suppuration. Suppura-

tive nodes should be aspirated. Excision or drainage may be necessary.

## Acute Infections Nonbacterial Gastroenteritis

**Definition.** So-called nonbacterial gastroenteritis or viral enteritis is an acute self limited infection of diverse etiology. The afebrile type is characterized by watery diarrhea, abdominal cramps, nausea and vomiting. An unrelated febrile type is non diarrheal. Both are apparently due to viruses as yet not cultivated. Febrile diarrheal disease, especially in children, may be caused by certain enteroviruses.

**Incidence and Epidemiology.** The disease is worldwide. The epidemiological unit seems to be the family, in which nonbacterial gastroenteritis may rank second to common respiratory disease in frequency. Both sexes and all ages are affected. The mode of transmission is fecal-oral. The afebrile disease, which is highly communicable, occurs in large epidemics, more frequently in the cold months and also sporadically. The incubation period ranges from one to five days, averaging three days. The febrile type has an incubation period of one or two days and is less contagious than the afebrile form. The epidemiology of the diarrheas due to enteroviruses is complicated by the high carrier rate in healthy children.

**Etiology and Pathology.** The causative agents of the afebrile and febrile types have not been propagated in the laboratory

but human volunteers were infected when fed bacteria free fecal supernates. Volunteers were actively immune to one strain of the afebrile agent for a year, but there may be antigenic variants. The afebrile agent passes through ultrafilters. Neither disease causes fatalities. The afebrile type is a rare terminal complication in patients ill of other disease, especially the aged. The pathological findings, consisting of intestinal hyperemia and occasional ulceration, can be attributed to hypermotility. The enteroviruses which induce diarrheal disease are usually members of the ECHO group, but polioviruses or Coxsackie viruses sometimes cause gastroenteric symptoms and signs.

**Symptoms.** The onset of the afebrile type is often abrupt with profuse watery diarrhea, anorexia, nausea and vomiting occurring singly or in combination. Usually there are hyperperistaltic abdominal cramps, often preceding a watery stool. Dizziness, mild headache and malaise are frequent complaints. When there is fever, it is low and related to mild or moderate dehydration. The abdomen is relaxed and the colon distended with gas, may be palpated. Borborygmi are heard and felt. Respiratory symptoms and signs are often conspicuously absent; if present, they may be adventitious. The blood count and other clinical laboratory values are normal and the feces seldom contain blood, pus or mucus. The acute illness lasts only a day or so, although stools may be loose for a week.

The febrile type differs in that there is no watery diarrhea; some patients are constipated. Abdominal pain tends to be persistent, is frequently intense and is often accompanied by moderate fever, headache and malaise. Patients recover within two days.

Children suffering from diarrhea due to an enterovirus may exhibit fever, vomiting and abdominal pain. Blood and mucus may occur in the stools. The disease is usually self limited.

**Diagnosis and Treatment.** Culture and microscopy of the feces are important in differentiation of nonbacterial gastroenteritis from salmonellosis, shigellosis or amebiasis, particularly in epidemics of the afebrile type. Absence of fever or leukocytosis may be helpful. Food poisoning can often be excluded by the distribution and timing of new cases which may continue to appear for over a week. Febrile nonbacterial gastroenteritis can resemble early

acute surgical conditions but it fails to progress and is soon over. A cytopathogenic agent can be isolated in tissue culture from feces of patients with enterovirus infection. The virus carried may be unrelated to illness, so isolation of an enterovirus from the stool is of little diagnostic value unless accompanied by demonstration of an increase in serum antibody.

Treatment is rarely needed and consists only of fluid replacement.

## RICKETTSIAL DISEASES

### Introduction

The rickettsial diseases of man are caused by microorganisms which are classified as a family (*Rickettsiaceae*) between the bacteria and the viruses because they have characteristics in common with both. These microorganisms were named "*rickettsiae*" to honor the observation made by Dr H T Ricketts in his studies of Rocky Mountain spotted fever and epidemic typhus fever. In 1910 while investigating the etiology of typhus Ricketts contracted this disease and died. Several species of rickettsiae are now recognized as pathogenic for man. Their individual characteristics are described in the sections dealing with the various human infections which they induce. In general the rickettsiae have four common features: (a) they are pleomorphic coccobacillary forms readily visible in the ordinary light microscope; (b) they multiply only within certain cells of susceptible animals; (c) they occur in various arthropods in nature; and (d) they cause acute febrile self-limited illnesses in man, most of which are accompanied by a skin rash.

The principal rickettsial diseases are divided into groups as indicated in the accompanying table.

The distinctive clinical course typical of each disease has been the primary basis for the classification shown in the table. There are also differences between the usual mode of transmission. The specific immunological properties of the rickettsiae and their differences biologically as revealed in laboratory studies are more valuable and more reliable in the classification of the rickettsial diseases than either the clinical features or the arthropod vectors. After recovery from any one of the individual diseases shown in the table the blood serum of man and certain animals has highly specific antibodies in complement fixation or rickettsial agglutination tests. These serological procedures not only indicate the main group to which a particular disease belongs but also distinguish between the members of the same group in certain instances.

Before specific serological techniques with rickettsial antigens were fully developed the Weil-Felix test was the only simple procedure available for laboratory differentiation of the rickettsial diseases. The Weil-Felix test is described in the section on the diagnosis of typhus fever. The basis of the reaction is believed to be a fortuitous occurrence of a common antigenic component between some rickettsiae and certain strains of the bacillus *Proteus vulgaris*. It should be emphasized that there is no etiological relationship between rickettsial diseases and the strains of *Proteus vulgaris* used in the Weil-Felix test. Although this test is immensely helpful in epidemics of classic typhus and in the investigation of scrub typhus it has important limitations and no longer serves as a primary criterion in the identification and classification of rickettsial diseases.

The immunity produced by the rickettsial diseases is usually of long duration. The members of one group confer either partial or complete immunity to the other diseases of the same group but no cross immunity occurs between the different groups. Unfortunately there are several instances of fatal infections among laboratory workers which emphasize this point; for example, tsutsugamushi disease has taken the lives of persons who had previously experienced epidemic typhus.

The rickettsial diseases include one of the notorious diseases of medical history, epidemic typhus fever, which has been a scourge of mankind for more than four centuries, as well as two "new" diseases not recognized clinically before 1935 (Q fever) and 1946 (rickettsialpox). Some of the rickettsial diseases such as murine typhus are world-wide in distribution; others are known only in certain areas; for example, rickettsialpox. It is of considerable interest that microorganisms indistinguishable in appearance from pathogenic rickettsiae are found as harmless symbionts in many different arthropods. Students of the rickettsiae, particularly Wolbach and Zinsser, have stressed the possible occurrence of rickettsial diseases whenever man, rodents and ectoparasites common to both are

<sup>5</sup> In addition to the diseases listed there are others which probably belong in this group such as North Queensland tick typhus tick borne rickettsioses of India and Kenya

<sup>6</sup> Bergey's Manual classification *Rickettsia rickettsii*

<sup>7</sup> *Dermacentor andersoni* *D. variabilis* *Amblyomma americanum*

<sup>8</sup> Bergey's Manual classification *Rickettsia conorii*

<sup>9</sup> *Rhipicephalus sanguineus*

<sup>10</sup> *Amblyomma hebraeum* *Haemaphysalis leachi*

<sup>11</sup> In author's opinion name *Dermacentor venustus akari* would be preferable

<sup>12</sup> *Allodermanissus sanguineus*

<sup>13</sup> *Trombicula akamushi* *T. deliensis*

<sup>14</sup> *Rickettsia diaporica* was the name first used for the American variety of Q fever rickettsiae

closely associated. Indeed the list of rickettsial diseases in the accompanying table indicates only the principal human rickettsial infections. For example a disease called North Queensland tick typhus has been reported from Australia (1947) which

probably is a member of the Rocky Mountain spotted fever group but it has not been completely characterized. trench fever or Wolhynian fever is reputed to be a rickettsial disease of man transmitted by the human body louse from man to man yet

its position in respect to the other rickettsiae has not been established

One final point of general interest in respect to the rickettsial diseases should be mentioned. Recent developments have added enormously to the means for combating these infections. Satisfactory vaccines have been prepared on a large scale against some of the rickettsial diseases. The methods for rapid mass delousing with the insecticide DDT have demonstrated how effectively the once dreaded epidemics of typhus can be sharply arrested. Finally several of the new anti-microbial drugs if used early in the illness have a dramatic effect on the clinical course of the rickettsial diseases. These advances greatly reduce the severity and the magnitude of the problems associated with the rickettsial diseases.

## The Typhus Group

**Definition** Typhus fever is an acute infectious disease characterized by severe headache, sustained high fever, generalized macular or maculopapular rash, and termination by rapid lysis in approximately two weeks.

Three diseases compose the typhus group: epidemic louse-borne typhus fever (Brill-Zinsser disease) and murine flea-borne typhus fever. Clinically and pathologically these three illnesses are nearly identical, differences occurring only in the intensity of the symptoms and signs, the severity of the course, and the case-fatality rate. Epidemiologically and historically, however, the three members of the typhus group are so different that they are described in separate sections.

### EPIDEMIC LOUSE-BORNE TYPHUS FEVER

(Classic Historic Human European Typhus, Jail Fever, War Fever, Camp Fever, Flea Fever [German]; Typhus Exanthématique [French]; Tifus Exantemático, Tabardillo [Spanish]; Dermotyphus [Italian])

**History** It is probable that typhus fever has afflicted mankind since ancient times, but the account of Fracastorius in 1546 is the earliest medical record which describes typhus fever with sufficient accuracy to permit its definite identification. The word typhus is derived from the Greek *typhos*, meaning smoky or hazy. Although the term had been used by Hippocrates to describe a confused state of intellect with a tendency to stupor, it was not applied to cases which were clearly typhus fever itself until 1760. Despite the work of Fracastorius, typhoid and typhus fevers were usually regarded as one entity by physicians until 1837, when Gerhard in Philadel-

phia clearly differentiated the two disorders on the basis of important differences clinically and pathologically. Even today, however, confusion in terminology persists in those parts of Europe where typhoid fever is called typhus abdominalis.

Typhus fever has had a major role in the history of the past four centuries. It followed in the wake of wars, famines, and human misfortunes of all kinds. It has often had a more decisive effect on military campaigns than the actual battles themselves. A subject admirably treated by Zinsser in his book *Rats, Lice and History*. The typhus epidemics in eastern Europe and Russia between 1918 and 1922 are estimated to have caused 30,000,000 cases and at least 3,000,000 deaths. It is worthy of comment that the ravages of typhus have characteristically been even greater among medical personnel than among the general population. In the 1915 epidemic in Serbia, nearly all of the 400 doctors in that country contracted typhus, and 126 died. Thus typhus has established its reputation as one of the major epidemic diseases.

**Etiology and Transmission** In 1916 da Rocha Lima showed that typhus was caused by the microorganism which he named *Rickettsia prowazekii*. This microorganism has been found in nature only in man and the human louse *Pediculus humanus*. Several other species can be experimentally infected with *R. prowazekii*—for example, monkeys, guinea pigs, cotton rats, gerbils, mice, fleas, and developing chick embryos. The numerous instances of typhus fever among laboratory investigators working with experimental typhus infection clearly indicate the validity of the conclusions reached by Wolbach, Todd, and Palfrey in their classic monograph on the etiology of typhus fever (1922).

The microorganism is present in the blood of typhus patients during the febrile period, particularly in the first few days of the illness. Human lice feeding on the patients ingest the typhus rickettsiae, which then multiply within the lining cells of the intestinal tract of the louse. The cells become greatly distended with masses of *R. prowazekii* and may burst into the lumen of the gut, whereupon the microorganisms invade other lining cells or pass out of the louse in the feces. After several days the louse gut becomes occluded by the distended typhus-infected cells, and the louse dies of intestinal obstruction. Chronic infection of lice with typhus rickettsiae has not been demonstrated. The microorganisms do not pass to new generations via the louse egg.

When the louse feeds, it makes a small puncture in the skin, secretions of the louse introduced during the act of feeding irritate the skin, causing the bitten person to scratch. It is characteristic of the louse that it defecates as it feeds, so that conditions are ideal for the rubbing of typhus

FIG 15 Temperature curve in a case of classic epidemic typhus (Courtesy of Dr T M Rivers Varal and Rickettsial Infections of Man J B Lippincott Company)

rickettsiae into the skin punctures. Two factors explain the movement of typhus infected lice from the persons whose blood has infected them to normal persons: the insects tend to leave a patient who has a high fever if other hosts are available and if the host dies of typhus the body becomes cold and the lice promptly crawl away in search of another host. These facts probably account for much of the transmission of typhus during epidemics.

Another important way in which transmission may occur is by contact with infected louse feces. The garments of a typhus patient toward the end of his febrile course and for several days early in his convalescence are contaminated by large quantities of louse feces containing viable typhus rickettsiae. Agitation of the garments disperses many particles of infected feces into the air of the room so that they may gain access to the respiratory tract or the conjunctivas of persons thus exposed. It is possible therefore to become infected with typhus without being louse infested at any time.

**Morbid Anatomy.** The typhus rickettsiae invade the endothelial cells of small arteries, capillaries and venules. The affected cells tend to proliferate and the injury soon results in thrombus formation with small areas of necrosis and perivascular accumulations of phagocytic cells. The lesions thus produced are sometimes referred to as typhus nodules and are scattered throughout the various organs and tissues, particularly the skin, the brain and the heart muscle.

Bacterial bronchopneumonia is a frequent finding at autopsy in patients who did not receive specific therapy. When penicillin or sulfonamides have been used

an interstitial pneumonitis may be observed which is ascribed to the typhus rickettsiae themselves when death is delayed to the third week of the disease. A necrotizing fibrinoid arteritis has been encountered which is similar to that found in numerous clinical conditions including hypersensitivity infection or renal disease (McAllister).

**Pathological Physiology and Chemistry.** Although epidemic typhus has developed in millions of patients, there have been remarkably few studies of the physiology and chemistry of this illness. The explanation of the paucity of data lies in the association of typhus epidemics and human misery. The disease breaks out under precisely those conditions which make hospitalization, medical care and scientific investigation largely impossible.

Suspensions of living, fully virulent typhus rickettsiae are toxic for white mice, producing death in a few hours. This phenomenon has not been explained biochemically or physiologically. Possibly the toxicity of rickettsiae is responsible for some of the clinical features of the disease. On the other hand, the widespread distribution of lesions in blood vessels can account for many of the manifestations of the illness in man.

It is characteristic of typhus that a severe hypotension may occur, often followed by evidence of renal insufficiency with a drop in urea clearance and a rise in blood urea nitrogen. Oliguria and fixed specific gravity of the urine accompany the other findings. If the patient recovers, a diuresis is often noted concomitant with improvement in clinical condition.

The plasma volume of several patients measured at various stages of typhus was found to lie within normal limits despite clinical impressions that dehydration was a feature of the clinical course in untreated cases. Usually the hemoglobin and the plasma albumin values fall below normal and a rise in plasma globulin is observed, particularly in the second week of the untreated disease (Yeomans).

When typhus occurs in a previously immunized person or when specific treatment is instituted early in the disease, the abnormal findings described above may be entirely absent.

**Symptoms and Clinical Course.** *Untreated Nonimmunized Patients.* The incubation period of typhus is approximately ten days to two weeks. The onset may be preceded by variable prodromal symptoms such as lassitude, headache and mild anorexia. More often the onset is abrupt with a severe

headache and generalized aches and pains over the entire body. The temperature rises in the course of two or three days to 40° C (104° F) and usually remains above this value for ten to fourteen days subsiding by rapid lysis in three or four days if recovery is to ensue (Fig. 15). Death occurs between the ninth and the eighteenth days in about 20 per cent of patients (for all age groups) during epidemics.

One or more shaking chills may occur at the onset. Unproductive cough may be troublesome. Constipation is more frequent than diarrhea. Other symptoms and signs are sometimes present but the most constant and characteristic feature in the first week of illness is the severe headache which resists all attempts to alleviate it with the usual drugs.

Toward the end of the first week the patient may appear to be slightly deaf. His face may be flushed and dusky. His conjunctivas are suffused and photophobia is usually apparent. The pulse is often some what slower than is expected with a fever of 40° C or more. The blood pressure is below normal. A macular or maculopapular rash usually appears between the fourth and the seventh days (most commonly on the fifth day) on the back and chest spreading later to the abdomen and the extremities but sparing the face, palms and soles except in severely ill patients.

The lesions are 1 to 4 mm in diameter with somewhat irregular outlines and when first apparent are pinkish to reddish in color. At first they fade on light pressure but later become fixed. The rash lasts about as long as the fever rarely being visible in convalescence. During the second week the lesions often become dark red or purplish as small hemorrhages occur in the lesions. Frankly purpuric or confluent rashes are observed only in severe cases which usually end fatally.

During the second week of typhus the pulse becomes more rapid. The patient tends to be stuporous or to have bouts of active delirium followed by profound stupor. This may progress to coma in severely stricken patients. Skin necrosis over the sacrum and other pressure points may occur. Otitis media and bacterial bronchopneumonia are frequent complications. Gangrene of the toes, the fingers, the penis, the scrotum, the ear lobes or the tip of the nose may appear. Parotitis sometimes bilateral often develops toward the end of the second week. Pneumonitis may be present and is often found more easily

by roentgenographic than by physical examination.

Death from typhus usually occurs after gradual progression from stupor to coma. Less often there may be peripheral vascular collapse with a fall in body temperature and death after a short period of unconsciousness. Rarely a convulsion may bring an abrupt end to an illness which had not seemed particularly severe.

*Typhus Fever in Previously Immunized Persons.* The symptoms and clinical course of epidemic typhus are greatly modified as a consequence of active immunization which has been widely used in recent years since the development of formalin treated rickettsial vaccines. "Adequate immunization" is defined in the section on Prevention and Control. The clinical course in "adequately immunized" persons varies from an illness characterized only by a mild headache and slight fever of one or two days duration to an illness of several days with a rash consisting of a few macules which disappear in a day or two. Complications are rare and the diagnosis often cannot be established except by laboratory tests. The mortality is close to zero.

*Typhus Fever Modified by Specific Treatment.* Although clinical experience with the tetracycline drugs and chloramphenicol is less extensive in epidemic typhus than in scrub typhus and Rocky Mountain spotted fever, the data at present indicate the probability of entirely similar beneficial results particularly if treatment is started early in the disease. Thus any one of these drugs may be expected to arrest the clinical course of typhus at whatever stage is present when they are first administered. They should bring about a drop in temperature to normal in thirty six to seventy two hours. Clinical recovery depends on the rate of healing of the widespread vascular lesions of typhus which may take several days depending upon the extent of their development when therapy was begun.

*Diagnosis.* *Clinical Diagnosis.* Before the characteristic rash appears it is impossible to assert on clinical grounds alone that a patient is suffering from epidemic typhus. The early stages of several acute infectious diseases closely resemble the first few days of epidemic typhus—for example small pox, relapsing fever, malaria, typhoid fever, meningococcal infection, yellow fever, the other rickettsial diseases and so on. The typhus rash is a distinguishing feature of considerable value; the first lesions appear on the trunk and later spread to the ex-

tremities sparing the face palms and soles except in severely ill patients This is helpful in distinguishing between typhus fever and Rocky Mountain spotted fever The typhus rash however is not present in 10 to 15 per cent of cases and may be difficult to recognize in dark skinned subjects The clinical diagnosis of epidemic typhus is particularly difficult in children or in persons who have previously received immunization In such instances a rash may be detected for short intervals only or may be entirely absent the symptoms are much less severe and the fever may persist for only a few days

**Laboratory Diagnosis** **SPECIFIC SEROLOGICAL TESTS** Agglutinins for typhus rickettsiae and complement fixing antibodies for specific rickettsial antigens appear in the serum of patients beginning about the end of the first week of the illness The titer rises toward the end of the illness and during the first and second weeks of convalescence tending to subside slowly thereafter In some instances persons recovered from typhus still show significant titers in their serum for months or years after an attack of the disease Sometimes on the other hand the specific antibodies may be no longer detectable a few weeks after the illness The use of killed rickettsial vaccines for active immunization often is followed by the development of specific antibodies which may add slight confusion to the interpretation of complement fixation tests taken during the course of a febrile illness The most important point in the serological diagnosis of typhus by specific rickettsial tests is the demonstration of a rise in titer from the early stage of the disease to a later stage A fourfold change in value is usually considered diagnostic

The rickettsial antigens prepared from infected yolk sac suspensions must be processed to eliminate a factor ordinarily present in the yolk sac which results in falsely positive complement fixation tests if the patient has positive serological tests for syphilis The antigens currently being prepared in this country are free of this cross reacting factor The specific antibodies for the typhus group serve to distinguish it clearly and definitely from the other rickettsial diseases Any laboratory which is able to perform routine complement fixation tests can purchase rickettsial antigens and perform specific diagnostic tests for the typhus group although the antigens are relatively more expensive than those for other tests

**WEIL FELIX TEST** Strains of the bacillus *Proteus vulgaris* referred to as OX 19 OX 2 and OX K have been relied upon in the past for the diagnosis of epidemic typhus As indicated in the Introduction the basis of the Weil Felix reaction with these strains of *P. vulgaris* is an accidental occurrence of an antigenic component common to both *Proteus* and the rickettsiae Usually patients suffering from a disease in the typhus group develop agglutinins for *Proteus* OX 19 The titer rises from a low level to more than 1:160 in most instances Furthermore some of the members of the Rocky Mountain spotted fever group likewise agglutinate *Proteus* OX 19 Thus the test does not distinguish between the two groups As ordinarily performed the reaction is carried out in test tubes with either living or killed suspensions of *P. vulgaris* in the smooth nonmotile form Slide tests developed by various workers are helpful during epidemics since the result may be obtained at the bedside in a matter of minutes with reasonable accuracy if suitable controls are performed

**ISOLATION OF RICKETTSIAE FROM THE PATIENT** The laboratory diagnosis of typhus may be made by inoculation of blood from a patient into susceptible species such as cotton rats guinea pigs or chick embryos if facilities are available for the further manipulations required to establish the identity of the microorganisms thus obtained The procedure is somewhat complicated and suitable only for specially equipped laboratories Colonies of human body lice may be used with success in the detection of living rickettsiae in patients Biopsy of skin lesions might also be of diagnostic help in the hands of an experienced pathologist

**Prognosis** The case fatality rate in epidemic typhus is less than 10 per cent in children As age increases the fatality rate rises until in persons over fifty it is 60 per cent or more However active immunization and the use of specific therapy greatly affect the mortality figures

In the absence of specific treatment the appearance of renal insufficiency is an early sign that a patient's illness will be severe or fatal The extent and severity of the typhus rash are roughly indicative of the severity of the disease Complications such as bronchopneumonia or gangrene of the skin are likewise serious prognostic signs A fall in systolic blood pressure to values below 80 mm of mercury for a few hours or longer may cause damage from which the patient may not recover even though the

blood pressure rises after the period of severe hypotension

When epidemic typhus occurs in persons who have received "adequate immunization" the prognosis is excellent unless the exposure to infection has been overwhelming

**Treatment** The tetracyclines and chloramphenicol are highly effective if administered early in adequate dosage by mouth. The clinician must decide on the basis of his own preference which of these drugs he will use. The initial dose for adults is 2 to 3 gm. split into three parts at hourly intervals. This should be followed by a maintenance dose of 0.5 gm. every six hours until the patient's temperature is normal. The dose may then be cut in half and continued for at least two or three days.

If treatment is terminated too soon the fever and symptoms may recur but will respond promptly when antimicrobial therapy is resumed.

Penicillin and streptomycin may have slight activity against typhus rickettsiae but their use in the clinical course of epidemic typhus should be considered only when secondary infections which respond specifically to penicillin or streptomycin are present. The sulfonamides may have a harmful effect on the course of typhus and should not be given.

Persons who handle typhus cases should be actively immunized. A louse infested typhus patient on admission to the hospital should be bathed and dusted with DDT. His garments should be sterilized. It is not necessary to shave the patient in order to achieve satisfactory delousing with DDT.

**General Supportive Care** Good nursing care is of great importance in the management of a patient with epidemic typhus. A rise in temperature above 105° F. is an indication for prompt administration of cold packs. Barbiturates and morphine are to be avoided if possible. Codeine may be tried for relief of headache but is likely to be ineffective. It is expected that the use of the new antimicrobial drugs will so alter the clinical picture of typhus that many of the recommendations and precautions in general supportive care of patients will be obviated. The reader is referred to the excellent account by Yeomans for further details in the management of epidemic typhus.

**Prevention and Control** The accomplishments in prevention and control of epi-

demic typhus during World War II constitute a milestone in the history of preventive medicine. Active immunization by means of killed rickettsial vaccines is now possible on a wide scale and has a profound effect on the severity and mortality of the illness. "Adequate immunization" consists in an initial course of two subcutaneous inoculations of 1 ml. each ten days to two weeks apart followed by stimulating doses of 1.0 ml. each at intervals of a few months if exposure is expected. The American military forces prefer the Cox type vaccine derived from the yolk sac membrane of developing chick embryos. "Adequate immunization" probably reduces the incidence of typhus fever among exposed persons; it definitely reduces the mortality close to zero and greatly lessens the severity of the illness.

DDT as a 10 per cent powder effectively delouses large numbers of people quickly if the dust is blown up the sleeves down the neck and around the waistband with a hand duster or a power duster. In recent years the human body louse in some areas of the world has become resistant to DDT. Under these circumstances other insecticides must be relied upon for the elimination of louse infestation. If our knowledge of prevention and control is properly applied it should be possible to eliminate outbreaks of typhus before they achieve serious proportions.

### BRILL ZINSSER DISEASE

(Brill's Disease Recrudescence Typhus)

**History** Nathan Brill after observing an epidemic of typhoid fever in the Mount Sinai Hospital in New York City subsequently encountered sporadic cases of an atypical typhoid-like disease in which the Widal tests and blood cultures were negative. In 1910 he reported 235 such cases and called attention to their several common features. The disease usually occurred in immigrants from Russia or Poland; there was no infectiousness (only in one household did a second case occur); headache, fever, and malaise were the prominent symptoms; and the most characteristic aspect of the disease was a macular or maculopapular rash beginning on the fifth or sixth day. Clinicians in other large cities of the eastern United States promptly reported cases which were referred to as Brill's disease. In 1912 Anderson and Goldberger showed by cross immunity tests in monkeys that Brill's disease was a form of typhus.

During the period from 1917 to 1932 the work of several investigators established the existence of two distinct varieties of typhus fever: the first caused by *Rickettsia prowazekii*, classic epidemic typhus spread from man to man by the human body louse; the second caused by *R. mooseri*, the murine variety of disease in rats spread from rat to rat by the rat louse and the rat flea and occasionally transmitted from rat to man by the rat flea. Since Brill's disease could not be ascribed to human lice or to rat fleas

## BRILL ZINSSER DISEASE

## EPIDEMIC LOUSE BORNE TYPHUS

Past history of typhus	Yes	No
Occurrence of cases	Sporadic	Epidemic
Transmission	Cases can occur without lice	By infected lice
Usual duration of fever	7 to 11 days	12 to 18 days
Complement fixing antibody with specific epidemic antigen		
(a) On 8th day of illness	More than 1000	Less than 100*
(b) Maximal titer occurs	Between 8th and 10th day	Later than 12th day
Complement fixing antibody with specific murine antigen	Titer moderately high (usually 2 to 8 fold less than titer with epidemic)	Absent or low titer (at least 3 <sup>+</sup> to 64 fold less than titer with epidemic)
Proteus OX 19 titer†	Usually less than 160	Usually from 320 to 5000

\* Titers refer to denominators of serum dilutions

† By the concentrated antigen method (U S Army Medical Service Graduate School)

however this differentiation of typhus fever into louse borne epidemic and flea borne murine did not establish the position of Brill's disease as either one or the other. It is unfortunate that many writers have erroneously used the term Brill's disease to describe sporadic cases of murine typhus.

**Etiology and Transmission** In 1934 Zinsser and Ruiz Castaneda isolated typhus rickettsiae from three Brill's disease patients. Their strains were similar to classic epidemic strains using the tests available for differentiation at that time. On the basis of this information and his analysis of 538 cases of Brill's disease in Boston and New York Zinsser advanced his hypothesis that Brill's disease represents a recrudescence of an old typhus infection implying that the epidemic typhus rickettsiae once acquired remained latent for many years somewhere in the tissues of infected human beings. According to Zinsser, Brill's disease cases when occurring in louse infested communities might become foci of outbreaks of epidemic typhus thus over the centuries man might be the reservoir serving to maintain the disease between epidemics.

Zinsser's hypothesis has been firmly established by recent studies. Murray and Snyder have obtained seven new strains of typhus rickettsiae from cases of Brill's disease in New York, Boston and Philadelphia. By means of several laboratory procedures not available at the time of Zinsser's studies it has been conclusively shown that all seven new strains of Brill's disease rickettsiae are indistinguishable from classic epidemic strains. Furthermore it has been clearly shown that human body lice become typhus infected by feeding on Brill's disease patients early in the disease. Virulent typhus rickettsiae have been recovered by Price (Price and others 1958) from lymph

nodes of two subjects many years after their original attacks of typhus.

Loeffler and Mooser (1952) suggested the name Brill Zinsser disease in recognition of Zinsser's brilliant contribution to knowledge of this disease.

Murray and co workers (1951) showed that Brill Zinsser disease occurred in Yugoslavia under conditions which precluded its explanation on the basis of transmission by body lice.

The main differences between primary epidemic typhus and Brill Zinsser disease are listed in the accompanying table (from Murray and Snyder 1953).

**Morbid Anatomy, Pathological Physiology and Chemistry, Symptoms and Clinical Course** The findings in Brill Zinsser disease under these headings are the same as those described under Epidemic Typhus with the exception that the illness is somewhat milder and definitely shorter in duration.

**Diagnosis** The clinical diagnosis of Brill Zinsser disease should be made when a fever of unknown origin occurs in a patient who has lived at some previous time in an area where typhus fever occurs in epidemic form who complains of an intense persistent headache and who has a macular or maculopapular rash on the fourth to the sixth day of the disease.

The laboratory diagnosis should be made by the complement fixation test (or the rickettsial agglutination test). Recent studies have shown that the Weil-Felix test should be ignored if negative.

**Prognosis and Treatment** The statements in the paragraphs on Prognosis and Treatment of Epidemic Typhus apply to Brill Zinsser disease as well.

**Prevention and Control** Since the factor or factors which precipitate an attack of

Brill Zinsser diseases are not known nothing can be said in regard to prevention and control of this illness

### MURINE FLA BORNE TYPHUS FEVER

(Endemic Typhus Rat Typhus Flea Typhus Urban or Shop Typhus of Malaya etc.)

History Murine typhus fever probably has occurred for centuries as a sporadic or endemic disease but only since 1931 has it been clearly distinguished from classic epidemic louse borne typhus. Sporadic cases of typhus were reported occasionally in Europe in the medical literature before Brill's disease was defined as an entity. Attention has already been called to the erroneous use of the term Brill's disease for cases of murine typhus a point which is again emphasized in the interest of clarity. Indeed several of the papers which prepared the way for the final differentiation of epidemic from murine typhus refer by title to Brill's disease although the cases under discussion were murine flea borne typhus.

In 1922 Hone reported several isolated cases from Australia and Wheatland described a noncontagious typhus like fever in the farm population of Queensland at a time when a plague of mice afflicted that part of Australia. Maxcy concluded that typhus in the southeastern United States must have a reservoir other than man and he mentioned mice and rats specifically. He further suggested that fleas mites or ticks could be the vector. Mooser in 1928 observed a basic difference in behavior of certain strains of typhus rickettsiae in the tissues of guinea pigs. Dyer and his colleagues isolated typhus rickettsiae from rat fleas in Baltimore (1931) and Mooser Zinsser and Ruiz Castaneda found the agent in rats in Mexico City. Mooser then named the disease murine typhus to indicate its presence as a natural infection of rats. Reports rapidly accumulated showing the world wide distribution of murine typhus. The distribution of the disease in the United States is shown in Figure 16 (page 97) which shows the five year attack rates of murine typhus and also the distribution and rates for Rocky Mountain Spotted Fever. Murine typhus has been reported from most of the states. The total number of cases between 1931 and 1958 exceeds 40,000. The reported incidence was increasing up to 1946 the decrease since 1946 has been attributed in part to the control measures which have been vigorously applied in certain states.

**Etiology and Transmission** Murine typhus fever is caused by *Rickettsia mooseri*. This microorganism is similar to *R. prowazeki* in size shape and staining properties. The disease is maintained in nature as a mild infection of rats transmitted from rat to rat by the rat louse or the rat flea. Neither the health nor the life span of the rat flea *Xenopsylla cheopis* is impaired by *R. mooseri* once infected the rat flea probably continues to excrete *R. mooseri* in its feces for the rest of its life. The eggs laid by infected female fleas do not transmit *R. mooseri* to the next generation of fleas. Man usually acquires the disease when bitten by an infected flea. In certain circumstances it is also possible that the ingestion of food recently contaminated by

infected rat urine or flea feces may result in murine typhus.

Unlike epidemic typhus murine typhus is maintained in nature independently of man by the rat flea rat transmission cycle. The disease is not spread from one patient to another. It has been reported that human body lice have been responsible for small outbreaks of murine typhus in which *P. prosoctus* has been transmitted from man to man in the same manner as described for *R. prowazeki*. This point cannot be settled until the more recently developed techniques for differentiation of epidemic from murine typhus rickettsiae are applied to the microorganisms involved in such outbreaks of presumed louse borne murine typhus. The point is of great interest however since it has been postulated that murine typhus rickettsiae may change to the epidemic variety as a consequence of man louse man passage. This must likewise be studied further before conclusions are justified.

**Morbid Anatomy** Information on the morbid anatomy of murine typhus is limited but it is usually assumed that the lesions are essentially the same as those in epidemic typhus.

**Pathological Physiology and Chemistry** Murine typhus has been even less well studied than epidemic typhus as regards abnormalities in physiology and chemistry. No important qualitative differences between the two diseases are recognized the deviations from normal in murine typhus being relatively infrequent and small in extent.

**Symptoms and Clinical Course** The incubation period of murine typhus lasts from six to fourteen days most often twelve days. The symptoms are similar to those of epidemic typhus. The principal differences between the clinical course of the two diseases are that murine typhus is milder and shorter the rash is less extensive and persists for shorter periods there are fewer complications and the case fatality rate is lower (less than 5 per cent for all groups).

It is impossible to distinguish an ordinary case of murine from a mild case of epidemic typhus solely on clinical evidence. Although epidemiological considerations are valuable it should be emphasized that murine typhus is world wide in distribution and may occur in the same localities as epidemic typhus.

**Diagnosis** *Clinical Diagnosis* The diagnosis of murine typhus is suspected when a patient has a sustained fever of several

days duration accompanied by headache generalized aches and pains and a macular rash appearing on the fifth or sixth day after onset of the fever. The rash is first noted on the trunk and later spreads to the extremities, the face, palms and soles are not involved. Since murine typhus is present in many of the places where Rocky Mountain spotted fever occurs, it is helpful to recall that the rash of the latter disease usually appears on the exposed extremities first, later involving the body and that it often appears on the face, palms and soles. The patient with murine typhus usually gives a history of activities likely to bring him into contact with places where rats are numerous, a feature which is valuable in directing attention to the possibility of murine typhus. Nevertheless, a definite recollection of a flea bite is often absent.

**Laboratory Diagnosis.** The diagnosis of murine typhus is usually established by serological tests as indicated in the section on Epidemic Typhus. The use of washed specific rickettsial antigens either in the complement fixation test or the rickettsial agglutination test permits the differentiation of epidemic from murine typhus. Usually there is more than a twofold difference in the titer of the patient's serum against the two antigens; the higher value being found against the homologous antigen. Some difficulty may arise if the patient previous to the attack of typhus had received antityphus vaccine. In such cases the titers may be identical. Specific antibodies appear early in the second week of the disease, increase in amount during the first part of convalescence and then subside slowly over a period of months. Some persons have demonstrable antibodies for years after an attack of typhus.

The Weil-Felix test described earlier does not distinguish between murine typhus and Rocky Mountain spotted fever. Consequently, the more specific rickettsial tests are preferred.

*Rickettsia mooseri* may be isolated from the blood of patients early in the disease by the inoculation of guinea pigs or rats. The scrotum of male guinea pigs often becomes enlarged a few days after inoculation with *R. mooseri* and the testes cannot be pushed back into the abdomen because there are adhesions between the layers of the tunica vaginalis. This is called the Neill-Mooser or the tunica reaction. It is not specific for murine typhus, however, and is no longer regarded as the principal criterion for the differentiation of epidemic from murine typhus.

**Prognosis.** Murine typhus is usually mild with fatalities only in the older age groups. The use of specific treatment is expected to reduce the severity of the illness.

**Treatment.** The comments on treatment as given in the section on Epidemic Typhus apply equally well to murine typhus.

**Prevention and Control.** The measures to prevent and control murine typhus are (1) use of DDT dust on rat runs to reduce the flea population of the rat colonies followed by (2) reduction of the rat population by poisoning, trapping, rat proofing buildings, eliminating rat harborage such as trash or rubbish piles and the like.

Vaccine suitable for human immunization is available and is recommended for persons who are likely to be exposed to murine typhus—for example, personnel engaged in rat control programs or laboratory workers. There is no justification for immunization of the general population since the attack rate is low and the measures for specific treatment are effective. It should be noted that murine typhus vaccine is not effective against epidemic typhus and vice versa. However, an attack of either disease protects man against an attack of the other in most instances.

## Rocky Mountain Spotted Fever

{Spotted Fever Tick Fever Tick Typhus  
[England] Fiebre Manchada [Mexico]  
Fiebre Petengal [Colombia] Febre  
Maculosa [Brazil]}

**Definition** Rocky Mountain spotted fever is an acute specific infectious endangitis chiefly of the peripheral blood vessels caused by *Rickettsia rickettsii* and transmitted by ticks. It is characterized by an onset with chills, continued fever of almost two weeks duration terminating in lysis, severe pains in the bones and muscles, headache, and a macular eruption becoming petechial which appears after the middle of the first week on the wrists, ankles and back, and then spreads over the whole surface of the body.

**History** The disease has probably existed in Idaho and Montana since the first settlement by white men and seems to have been known to the Indians before that time. It was first described by Surgeon Major W. W. Wood in 1896 in a report to the Surgeon-General Maxcy of Idaho and McCullough of Montana gave the earliest clinical descriptions of the disease. Important laboratory

and field investigations were made by Wilson and Chowning and by Ricketts and his associates. Ricketts established the transmission of the disease by the tick and defined most of the problems which have resulted in our present knowledge of the disease and its causation.

**Distribution, Transmission and Incidence** Rocky Mountain spotted fever is limited to the western hemisphere. However, closely related diseases occur throughout the world wherever Ixodidae have opportunity to feed on man; these include boutonneuse fever of the Mediterranean basin, South African tick bite fever, North Queensland tick typhus, and the tick-borne rickettsioses of India and Russia. Although the term "Rocky Mountain" is firmly fixed as part of the name for American spotted fever, it now implies too restrictive a distribution of the disease. This malady has been recognized throughout the United States except in Maine and Vermont, as well as in Canada, Mexico, Colombia, and Brazil. No animal has been definitely incriminated as the reservoir for *Rickettsia rickettsii*, but all small mammal hosts are suspect, particularly rabbits and field mice. Since the rickettsiae are transmitted transovarially by

## SPOTTED FEVER AND MURINE TYPHUS

5 YEAR ATTACK RATE PER MILLION BY STATES  
1952-1956

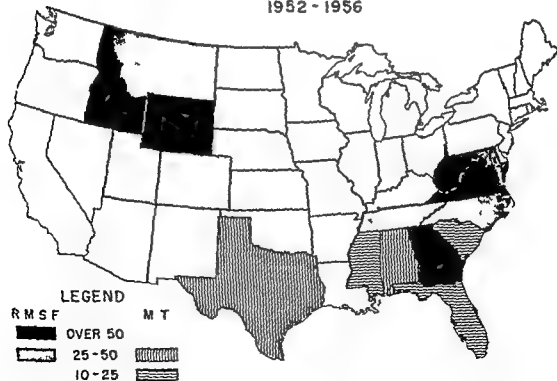

FIG. 1b. Incidence of spotted fever and murine typhus in the United States in recent years.

certain ticks these vectors probably serve also as reservoirs

Ten species of ixodid ticks have been found infected in nature in the western hemisphere this by no means exhausts the list of potential vectors of the disease. The seasonal periodicity of spotted fever in man in a given area is related to the life cycle of the local vector tick however the majority of cases occur in late spring and early summer.

Almost 500 cases occurred each year in the United States from 1935 to 1949 inclusive with a mortality of about 20 per cent. Following the introduction of specific antimicrobial therapy in 1948 the number of recognized cases decreased to about 300 annually and the mortality to nearly 3 per cent. During the five year period 1952-1956 the highest attack rate per million population occurred in Wyoming but Idaho, Virginia and West Virginia also had rates of over 50 per million. Rates of 25 to 50 per million population were noted in Montana, Utah, Colorado, Maryland, North Carolina, Tennessee and Georgia (see Fig. 16). In the West where the wood tick (*Dermacentor andersoni*) is the vector a relatively higher proportion of adult males contract the disease. On the other hand in the East where the dog tick (*Dermacentor variabilis*) is mainly responsible for transmission children and women are mainly affected. Occupational propensity to the vector is responsible for this distribution not variations in susceptibility of different ages and sexes.

The mortality varies with age being higher in adults than in children. Before the advent of specific chemotherapeutic measures the mortality rate for nonvaccinated adults in the Bitter Root Valley of Montana was about 80 per cent in contrast to 37.5 per cent for children. Topping pointed out that approximately half the patients in the western states were over forty years of age whereas in the East about this same proportion were under fifteen years. Little difference was noted in the fatality rates when patients from the two regions were compared on the basis of age.

**Etiology** *Rickettsia rickettsii* (Wolbach) Brumpt proved cause of Rocky Mountain spotted fever has a number of characteristics which distinguish it from the rickettsiae of the typhus and tsutsugamushi groups in addition to immunological differences. Prominent among these are its cyclic morphology in ticks, its hereditary transmission in ticks and its intranuclear as well

as intracytoplasmic growth in tick and mammalian tissues. It is distinguished from other rickettsiae of the spotted fever group by several types of immunological procedures. Strains of *R. rickettsii* vary considerably in their virulence for man and animals. A toxin associated with the etiological agent is capable of killing mice within a few hours; it is similar in many respects to the toxins of the typhus rickettsiae.

**Morbid Anatomy** The distinctive pathological changes of spotted fever are found in the small vessels and are observed microscopically. The gross changes often are unimpressive. The following description is taken from Wolbach:

The blood vessel lesions consist at first of a proliferative reaction of the endothelium followed by thrombosis either mural or occluding. A considerable degree of perivascular infiltration occurs. The causal agent of the disease is found in endothelial cells and also in smooth muscle cells of blood vessel walls. Arteries, veins and capillaries are affected. Minute focal lesions of the central nervous system accompanied by infarction of arterioles are common. In addition diffuse infiltrations by mononuclear cells, chiefly monocytes, are found in the heart, liver, spleen and in the alveolar walls of the lungs. Small areas of necrosis and considerable damage to the endothelium of the sinusoids are found in the liver.

**Pathological Physiology and Clinical Laboratory Findings** Harrell points out that in fulminating disease with death early in the first week the picture is that of peripheral vascular collapse. There is marked dilatation of capillaries and pooling of blood without increased capillary permeability or loss of fluid into extravascular spaces. As the proliferative and thrombotic lesions develop in the small vessels anoxia occurs in the areas supplied with the usual resultant effects including necrosis. In severe infections there is increasing capillary permeability with loss of water, electrolytes, proteins and erythrocytes. This and other contributing factors result in a decrease in plasma volume and in serum proteins and chlorides along with an increase in thio cyanate space and even clinical edema. Electrocardiographic changes consistent with edema and anoxia of the myocardium are found. Liver function is diminished as evidenced by slight elevation of serum bilirubin and marked reduction of hippuric acid excretion after benzoic acid administration. The elevated nonprotein nitrogen appears to be an extrarenal type of azotemia. These various abnormalities intensify one another and set the stage for the development of terminal peripheral vaso-

lar collapse. With recovery, whether natural or induced by antimicrobial therapy, most of the physiological abnormalities are rapidly corrected; however, loss of edema fluid and restoration of serum proteins may take several weeks in the patient who suffered severe disease. In the milder cases or in those given specific treatment early, the physiological observations are minimal.

The urine is that of any febrile disease. Moderate leukopenia with neutropenia is frequent during the first few days; eosinophils are decreased or absent. Subsequently, a mild leukocytosis appears with an increase in polymorphonuclear cells and a shift toward the left in the Schilling hemogram. During the second week, a normochromic normocytic anemia generally appears; hemoglobin values of 9 gm and erythrocyte counts of 3 000 000 per cu mm are common. The blood platelets remain within normal limits, but the prothrombin time may become somewhat elevated late in the disease. Increased capillary fragility is usually demonstrable by the tourniquet test.

The cerebrospinal fluid may be under slightly increased pressure and show a slight pleocytosis, especially in patients with severe cerebral involvement. Serological findings are discussed in the section on Diagnosis.

**Symptoms, Incubation.** The incubation period of the more severe infections is two to five days, and of the milder ones from three to fourteen days.

**Prodromal Stage.** Before the definite onset of the disease, there may be a few days of malaise accompanied by chilly sensations and loss of appetite. A prodromal stage is more evident in cases which prove to be relatively mild. The onset is usually accompanied by a chill, and there are severe general pains referred to the bones, muscles, back, and joints, particularly in the calf muscles, large joints, and lumbar region of the back. Headache is common and severe. The face is flushed, the conjunctivas injected, and the tongue white-coated with moist edges and tip. Constipation is usual. There is usually photophobia.

FIG 17 Rocky Mountain spotted fever. Photograph of skin lesions taken two days before death. (Courtesy of Dr. George E. Baker, Casper, Wyoming.)

FIG 18 Same patient as in Figure 17 illustrating coalescence of skin lesions which have become purpuric. Localized areas of necrosis are evident. (Courtesy of Dr. George E. Baker, Casper, Wyoming.)

and there may be epistaxis. A short dry cough is common. The patient is frequently ill enough to take to bed on the second day of symptoms.

**Temperature.** Before the initial chill there may be a slight evening elevation of temperature. After the chill the temperature rises fairly rapidly and reaches 102° to 104° F (38.8° to 40° C) by the second day. In nonvaccinated persons who contract the disease and do not receive specific therapy the fever continues to rise gradually to a maximum of 104 to 105° F (40° to 40.5° C) during the second week. In very severe cases in the Bitter Root Valley temperatures from 106° to 107° F have been recorded. The maximum temperature persists in untreated patients throughout the second week of the disease with slight morning drops then falls by lysis so that normal temperature is reached before the end of the third week. After recovery the temperature may be slightly subnormal for a few days. In fatal cases the temperature may drop to normal or subnormal and then rise eighteen to twenty-four hours before death which in severe cases usually takes place between the sixth and twelfth days of the disease.

The pulse is at first full and strong but gradually loses volume and strength and increases in rapidity out of proportion to the fever. During the height of the fever the blood pressure is markedly lowered as in typhus fever. The pulse rate ranges from 110 to 140 and may reach 150 a few days before death. A pulse rate of 120 with a temperature of 102° F is not uncommon. Electrocardiographic changes occur (see section on Pathologic Physiology).

The respiration behaves very much as does the pulse. It is rapid out of proportion to the apparent severity of the illness usually 30 to 40 a minute but increases occasionally to 60 before death.

**Eruption.** The rash appears most often on the third day of fever but may occur later during the first week or rarely on the second day. Occasionally it may be preceded by a mottled appearance of the skin of the face, neck and upper chest inconstant in appearance sometimes suggesting the onset of measles. It appears first on the flexor surfaces of the wrists and ankles and back then on the forehead, arms, legs, chest and abdomen. The efflorescence requires twenty-four to thirty-six hours although the eruption may appear still later than this on the palms of the hands, soles of the feet and scalp. The mucosa of the cheeks, palate, fauces and pharynx may show the eruption.

The temperature is not appreciably affected at the time of the eruption but the subjective symptoms ameliorate. The rash at first is in the form of rose-colored macules 1 to 4 or 5 mm in diameter not elevated not palpable and disappearing upon pressure. The skin may be tender at the site of the spots. The macules soon become deep red or purplish and increase in size often becoming confluent. After a few days the rash begins to persist upon pressure and then becomes generally petechial. Cutaneous and subcutaneous hemorrhages of considerable size occur frequently in severe cases and the skin in the second week of the disease may assume a glazed appearance. Where the skin is thin as over the thighs a peculiar dusky reddish or bluish mottling may often be seen which is due to stasis of blood in the subcutaneous vessels because of thrombosis. In mild cases the rash does not become confluent and the petechiae remaining small give a peculiar mottling which several Idaho physicians have compared to the markings of turkeys' eggs. Slight icterus may appear in the second week of the disease.

The rash begins to disappear with the subsidence of fever but may long be indicated by the persistence of pigmented spots. Necrosis of the skin of the scrotum, prepuce, fingers, toes, vulva, lobes of the ear and mucous membrane of the soft palate may occur in the third week. Desquamation follows recovery but is slight except where the lesions have been most marked. Minute cicatrices in the skin may persist for a long time after recovery. In very mild cases the rash may be limited to one extremity. In persons previously vaccinated the rash may be entirely absent.

**Neurological Symptoms.** Restlessness and insomnia are common throughout the disease constituting its most distressing features. Hyperesthesia may be severe. Delirium is usual in severe cases during the height of the fever and coma usually precedes death by a few hours or a day. Rarely convulsions, muscular rigidity and opisthotonus occur. After recovery deafness, visual disturbances, slurring speech and mental confusion have been noted for a few weeks.

**Complications and Sequelae.** Secondary pneumonia is the one important complication and it is infrequent. Circulatory failure and necrosis of tissue may be looked upon as resulting directly from severe pathological changes characteristic of the infection rather than as complications. Harrell has drawn attention to evidence of residual

damage in the heart and brain of certain recovered patients

**Immunity** Recovery from Rocky Mountain spotted fever is accompanied by complete immunity for a long period of years. According to Parker, second infections have been reported eight or more years after the first in some instances ending fatally. Guinea pigs recovered from feebly virulent strains are not fully protected against highly virulent strains. Recovery from virulent strains does confer complete and lasting immunity in animals.

A brief period of passive immunity may be conferred by the injection of blood from an immune animal.

Active immunity can be produced by the injection of chemically killed rickettsiae. The use of vaccine is discussed under Prophylaxis.

**Diagnosis** Theoretically the same diseases must be considered in the differential diagnosis of Rocky Mountain spotted fever as in typhus but practically the seasonal incidence of the disease and its prevalence in certain geographical areas eliminate a number of possibilities. Meningococcal infections and measles are the two diseases most liable to be temporarily mistaken for Rocky Mountain spotted fever. Culture of the blood and cerebrospinal fluid should be resorted to when there is a question of meningococcal infection since the rash may simulate that of Rocky Mountain spotted fever. Usually the more severe nervous symptoms with early rigidity of the neck and the character of the onset of meningococcal infection with meningitis should serve to differentiate the two. Measles at its height in children presents difficulty for the rash may closely resemble the early rash of spotted fever. The history of slower onset with coryza and lacrimation, the presence of Koplik's spots, the absence of severe muscular pains and the papular character and sequence of distribution of the rash are the most important differential data. Typhoid fever with a pronounced rash may also have to be excluded. The rash in typhoid fever however is more palpable and elevated than in Rocky Mountain spotted fever and is generally more restricted to the trunk. A slower pulse rate, lower fever, diarrhea and positive blood cultures or a positive Widal reaction make final exclusion simple.

Since Rocky Mountain spotted fever and endemic (murine) typhus coexist in at least twenty-three states, the problem of differential diagnosis often arises.

Spotted fever is essentially a rural dis-

ease and exposure to ticks is important. Most cases occur in the spring and early summer. Endemic typhus transmitted by the rat flea is predominantly an urban disease in the United States but has a rural distribution in certain areas of the South where peanuts are cultivated. It occurs most often in food handlers and peanut farmers whose premises are heavily infested with rats. In contrast to spotted fever, endemic typhus is more likely to occur in late summer and autumn.

The outstanding clinical difference is in the evolution and distribution of the rash. In endemic typhus it appears first on the chest and upper abdomen, usually spares the palms and soles and rarely involves the face and neck, wrists and ankles.

Final differentiation of spotted fever from endemic typhus and also from epidemic typhus in some Latin American countries often requires the use of specific complement fixation tests. This has become especially true since the introduction in 1948 of treatment with the antimicrobial drugs chloramphenicol and the tetracyclines; now these diseases may be cut short so early in their courses that the typical clinical picture never develops.

The Weil-Felix reaction is of some value in the diagnosis of spotted fever. All three types of *Proteus vulgaris* used (OX 19, OX 2 and OX K strains) may be agglutinated by the patient's serum, most often the highest titer is obtained with the OX 19 strain but occasionally with the OX 2 strain. A titer of 1:320 with a single convalescent serum is the lowest that can be considered of diagnostic importance but as in typhus a rising titer during the course of the disease is of greatest significance. A test should be made as early as possible in the disease and repeated after the tenth day. A significant reaction may not be obtained until convalescence has begun.

A differential diagnosis between Rocky Mountain spotted fever and the other rickettsial diseases should not be attempted by means of the Weil-Felix reaction.\*

The complement fixation technique using *Rickettsia rickettsii* as antigen provides a specific diagnostic test. Complement fixing antibodies usually appear during the second or third week in patients who receive no specific therapy but may be delayed a week or so in those treated early in the disease. No cross reactions are obtained with the typhus group but an appreciable number of cross reactions occur with diseases of

\* See Typhus Fever for further consideration of the Weil-Felix reaction.

the spotted fever group including mite borne rickettsialpox. The more highly purified antigens give fewer cross reactions.

**Prognosis.** The prognosis has changed radically since the introduction of treatment with chloramphenicol and the tetracyclines. Previously the overall mortality was about 20 per cent; now deaths are rare in treated patients and are limited essentially to those who first receive specific therapy late in the course of the disease. The prognosis in patients given only supportive treatment is best in vaccinated persons and in children and becomes progressively worse with advancing age or with secondary bacterial pneumonia.

Harrell indicates the difficulty of estimating the prognosis in an individual early case but his classification of stages of severity of the disease is of interest. Mild cases are those with negative tourniquet tests throughout the illness, no edema and stable pulse and blood pressure. Moderate cases show increased capillary fragility, slight clinical edema, tachycardia and toxic symptoms. Severely ill patients exhibit marked purpura, moderate edema, delirium, toxemia and vasomotor instability.

**Treatment.** The introduction since 1947 of the antimicrobial drugs chloramphenicol and the tetracyclines, which are markedly effective in the treatment of rickettsial diseases including spotted fever, has radically altered concepts of the therapy of this disease. Early diagnosis and the proper use of these new antimicrobials generally render the patient afebrile in a few days and the severe disturbances of physiological mechanisms associated with the classic disease are prevented or minimized. General supportive measures remain important, however, and their proper use in dangerously ill patients may tip the scale toward survival. Harrell has emphasized the similarity between the peripheral circulatory collapse of spotted fever and shock associated with burns and trauma. When such shock is present it should be treated vigorously in the usual manner: replacement of blood proteins by administration of plasma and by whole blood transfusions and restoration of blood volume with saline and glucose solutions are indicated. As in other forms of shock, these procedures should be carefully regulated on the basis of results of frequent chemical studies of the blood. Other general measures include those used for continuous fevers. The barbiturates are indicated if restlessness and insomnia contribute to exhaustion. Digitalis is rarely of value since the major circulatory disturb-

ances are of extracardiac origin. Penicillin is indicated in the presence of secondary bacterial pneumonia.

Chloramphenicol or a tetracycline is given orally in 2 to 4 gm amounts as a "loading dose" over a few hours followed by 2 to 4 gm daily in divided doses at six to eight hour intervals until the patient has been afebrile for a day or so. In patients too ill to take oral medication an intravenous preparation of one of the antimicrobials may be employed for the loading dose. Studies by Woodward's group at the University of Maryland and others (see Harrell) indicate that addition of cortisone to the usual chloramphenicol regimen produces a more rapid subsidence of fever and toxemia than antimicrobial therapy alone. This combined therapy should be considered for critically ill patients. A regimen of 200 mg of cortisone orally or intramuscularly followed by 100 mg doses at six hour intervals has been used for this purpose but cortisone should not be continued after the patient becomes afebrile or for longer than thirty-six hours. The minor untoward manifestations of treatment with the tetracyclines and chloramphenicol are well known as are the rare but serious blood dyscrasias associated with use of chloramphenicol. Fear of neither type of toxic response should inhibit the physician from using these life-saving drugs in spotted fever which if untreated has a high mortality, a long convalescence and occasional sequelae.

**Prophylaxis.** General measures for control of the disease are directed toward reducing the chance of contact with infected vector ticks and immunization against the rickettsial agent.

Recent advances have made personal prophylaxis, the avoidance of tick bites, more practicable than heretofore. Brennan has found that clothing treated with N-n-butylacetanilide gives excellent protection against nymphs and adults of *Amblyomma americanum*. Dimethyl phthalate, one of the standard Army insect repellents, has only a slight effect against ticks.

Persons exposed in endemic tick infested areas should be carefully examined for ticks. Daily stripping and thoroughly inspecting the entire body for ticks, particularly about the hairline of the neck and the perineum, is strongly recommended. Children should be inspected twice daily. The tick apparently cannot readily transmit the disease without having been attached for some hours.

Ticks which have attached should be re-

moved with care. Applying ether chloroform or kerosene to a tick or holding a lighted cigarette near it may cause the arthropod to detach. Otherwise forceps or tweezers should be used grasping the tick as close as possible to the point of attachment and applying gentle traction lest the mouth parts remain embedded in the skin. Every effort should be made to avoid crushing the tick and contaminating the bite site with its contents. Disinfect the area of attachment with soap and water and the wound proper with a toothpick dipped in crude phenol. Silver nitrate and iodine are less effective.

Measures for reducing the tick population have definite prophylactic value but because of their cost are rarely used primarily for the prevention of spotted fever in man. Clearing and cultivation of infested land renders such areas safe. Removal of ticks from live stock and dogs is an important control measure because these animals are regular hosts of adult *Dermacentor*. This should not be done by hand. A satisfactory dip for these animals is either 0.5 per cent chlordane or a combination of 0.025 per cent gamma isomer benzene hexachloride and 0.5 per cent DDT. Dust sprays containing these insecticides may also be used. None of these residual insecticides should be applied to cats which lick their fur and hence may be poisoned. Campaigns for the destruction of small mammals which serve as hosts for the larval and nymphal ticks may be practicable in special circumstances particularly when directed against cottontail rabbits. The rodenticide sodium monofluoracetate (Compound 1080) is most effective for this purpose but its high toxicity for men restricts its use to specialized personnel.

Direct attack on the tick vectors by chemical means is feasible in selected instances. Both DDT and chlordane give excellent control of *Dermacentor* and *Amblyomma* ticks when applied directly to the ground and to low vegetation in the form of solutions, dusts or emulsions at the rate of about 2.5 pounds of either chemical to the acre. In certain areas as in the northeastern United States 90 per cent of the local *Dermacentor* population is frequently found within 4 feet of roads and trails. Most of this assemblage of ticks is often concentrated within a few inches of the trail margin.

Vaccines containing chemically killed *Rickettsia rickettsii* are of value. Immunization comprises a course of three injections given in the spring before ticks become

plentiful. Vaccination has been one of the most important prophylactic measures for those habitually or occasionally exposed to spotted fever. It will no doubt continue to be useful for those at great risk but the availability of highly satisfactory therapeutic agents may be expected to reduce its need in those subjected to only slight risk of infection.

## Scrub Typhus

(*Tsutsugamushi* Disease, Mite Borne Typhus, Japanese River Fever, Tropical Typhus, Rural Typhus)

**Definition.** Scrub typhus is a self limited febrile illness of two weeks duration caused by *Rickettsia tsutsugamushi* transmitted by chiggers and distributed widely in the Asiatic Pacific area. It is characterized by sudden onset of fever accompanied by a primary skin lesion (eschar) and by the development of rash on about the fifth day.

**History.** Scrub typhus may have been known in South China during the sixteenth century but the earliest recognizable description of the disease was by Hashimoto in 1910. He noted that the disease (*tsutsuga*) occurred along the banks of the Shinano River in Japan and that the natives of the area believed it to be caused by the bite of a minute insect or mite (*mushi*). Although it was extensively studied by Japanese investigators after its original description the interest of Western physicians remained dormant until the disease was recognized in Sumatra and Malaya about twenty five years ago.

During World War II scrub typhus emerged from obscurity to occupy a position of great importance in military medicine. Philip tabulated the cases in the Allied Armies in the Pacific Southeast Asia India areas during 1942-1945 and found 18,450 incidents of scrub typhus; this tabulation is by no means complete. The United States Army had 243 deaths among its 6685 men who contracted the disease.

**Distribution and Incidence.** Scrub typhus occurs along the coastal regions of Asia

from Korea to India and among the islands of the western and southern Pacific from Japan to northern Australia.

There are no reliable statistics on incidence of the disease in civilian populations in the Asiatic Pacific area however it is possible to arrive at certain estimates. In the Shinano River area of Japan a survey made in 1947 among 2300 farmers whose occupation exposed them in infected fields during the mite season each year revealed 247 attacks during a total of 20 602 person years exposure. This gives an attack rate in which the patient recovered of twelve cases per thousand farmers per year. Because of limited geographical distribution of the disease in Japan the total number of cases is probably only a few hundred each year. The disease is more common in parts of Southeast Asia than in Japan. Selangor one of the states of the Federation of Malaya with an area about two thirds that of Connecticut and a population of about 400 000 reported 162 cases of typhus with 3 deaths in the first eight months of 1948.

High attack rates were attained during brief periods in certain Allied military groups during World War II. Among Americans at the Sansapor beach head in the Southwest Pacific 403 men of one regiment suffered the disease between the sixth and twentieth days after landing moreover the attack rate during the second week at Sansapor reached 900 cases per thousand troops per year. Similarly 18 per cent of one British battalion contracted scrub typhus during two months in Burma in 1944 and 5 per cent of the total strength died of the disease.

The mortality in scrub typhus has varied widely in different geographical areas and in different populations. The highest rates have been in Japan where 40 to 60 per cent of the diagnosed patients have succumbed. In Malaya during the past twenty years about 7 per cent of the cases terminated fatally. Even in the same general area and in a relatively homogeneous population viz. United States Army personnel in the Southwest Pacific the case fatality ranged between 0.6 and 35 per cent for the outbreaks at Ow Biak and Finchaven respectively. Many factors undoubtedly contribute to the variations in mortality of scrub typhus but it is well established that certain strains of *Rickettsia tsutsugamushi* are more virulent than others for laboratory animals and presumably this is also true for man.

**Epidemiology** Scrub typhus is transmitted

to man by at least two species of mites *Trombicula alamushi* and *T. deliensis*. Only the six legged larvae are parasitic on mammals and birds. The nymphs and adults both of which have eight legs also live in soil and vegetation but presumably feed on eggs of mosquitoes and other insects. The tiny (0.15 to 0.4 mm) red larvae attach themselves to the skin of the host and obtain a feeding of lymph or tissue juice. During the attachment infected larvae may transmit *Rickettsia tsutsugamushi* to the host or uninfected larvae may acquire rickettsiae from a host with active disease. The rickettsiae apparently maintain a symbiotic existence in the mite since their presence does not interfere with the development and propagation of the arthropod. In several of the *Trombicula* rickettsiae are transmitted transovarially from one generation to the next. Thus the mite serves both as the vector and as a reservoir of the causal agent. Various small rodents constitute the animal reservoir. In different regions these include rats, voles, shrews and field mice.

Endemic areas of scrub typhus occur in different types of terrain but are found most often in fields which through neglect have been permitted to become overgrown with scrub vegetation. The essential features of an endemic focus are (1) adequate ground moisture and warmth for the propagation and emergence of vector mites, (2) suitable rodent population and (3) the presence of *R. tsutsugamushi* in rodent hosts and vectors of the area. Because of the exacting requirements for a focus the endemic areas are often sharply delimited small islands of infection which present the same general appearance as surrounding uninfected terrain. Birds serve as hosts for vector mites and may help seed infection in nearby or distant areas.

Man is an incidental host for *Trombicula*. He contributes to the cycle of scrub typhus in nature by modifying the ecology of the region and thus influencing the rodent and mite populations. His occasional inadvertent infection with *R. tsutsugamushi* is unimportant in the maintenance of either the disease or endemic areas.

The seasonal incidence of human disease is dependent on the prevalence of mites. In the classic scrub typhus areas of Japan it is in the summertime that *T. akamushi* emerge and become numerous. However in certain Japanese islands where *T. scutellaris* is presumed to be the vector cases of scrub typhus occur in winter. In the subtropics and tropics cases occur throughout

the year whenever susceptibles are introduced into an endemic area but infections are more prevalent during the wet seasons.

**Etiology** *Rickettsia tsutsugamushi* (Haya shi) Ogata the etiological agent of scrub typhus is an intracellular obligate parasitic microorganism. It has the general properties of other rickettsiae pathogenic for man but is distinguished from them by its host range and by its specific immunological properties. Strains of *R. tsutsugamushi* vary in their virulence for animals and several strains yield a toxic material which in concentrated form kills mice within a few hours. All strains have certain specific antigens in common but the results obtained with a variety of immunological techniques indicate that the species *R. tsutsugamushi* is not antigenically homogeneous. The growth of *R. tsutsugamushi* in experimental animals is inhibited by a number of chemical substances. The three which have proved of value in the treatment of patients with scrub typhus are para amino benzoic acid, chloramphenicol and the tetracyclines.

**Morbid Anatomy** Macroscopic changes found at autopsy are not striking. The primary eschar may be present but no rash is seen. The body cavities contain moderate amount of serofibrinous fluid and the parenchymatous organs show cloudy swelling. The spleen is enlarged and there is generalized lymphadenopathy. Hemorrhagic pneumonia is usually present with superimposed secondary bronchopneumonia.

The basic histological lesions in scrub typhus as in other rickettsial diseases are disseminated focal vasculitis and a perivasculitis consisting of accumulations of monocytes, plasma cells and lymphocytes. Acute nonsuppurative myocarditis and encephalitis and an interstitial pneumonitis are found in almost all fatal cases.

**Clinical Laboratory Findings** There are no specific cytological or chemical changes in the blood in scrub typhus. During the first week of illness the total leukocyte count is normal or moderate leukopenia occurs. Leukocytosis generally indicates secondary bacterial infections. Anemia is rare but the erythrocyte count often becomes reduced slightly during the disease. In severely ill patients the plasma proteins may be moderately reduced. Plasma fibrinogen may be decreased in patients with impairment of hepatic function and the serum bilirubin may be slightly elevated. Profuse sweating and an inadequate intake of water and salts may produce disturbances of acid base equilibrium.

*Rickettsia tsutsugamushi* can be recovered from the blood of patients throughout the first ten or twelve days of fever. The agent is demonstrated indirectly: white mice inoculated intraperitoneally with the blood sample acquire typical disease and rickettsiae are found on microscopic examination of stained smears of their peritoneal scrapings. Late in the second week agglutinins for the OXK strain of *Bacillus proteus* appear in the patients' blood.

**Symptoms** After an incubation period of six to eighteen days generally ten to twelve illness begins suddenly with headache, feverishness and intermittent chilliness. The conjunctivas are injected; there is generalized lymphadenopathy and in the majority of Caucasians a primary lesion or eschar at the site of attachment of the infected mite may be found. The temperature may increase stepwise during the first week to levels of 104 to 105 F or it may rise abruptly to such levels on the first or second day and remain elevated. About the fifth day a red macular rash appears on the trunk and may extend to the arms and legs. It usually persists for several days but may disappear within a few hours. The rash like the eschar is more often absent than present in Asian patients with scrub typhus.

The pulse during the first week is relatively slow, usually 70 to 100 per minute. Nonproductive cough is commonly present and rales and rhonchi are generally heard. Roentgenographic evidence of pneumonitis is found in about one fifth of the patients. Despite the sustained high fever the severe discomfort from headache and the apathy patients rarely appear dangerously ill during the first week.

The temperature remains elevated during the second week and even the less severely affected persons begin to show the debilitating effects of sustained illness. The relative bradycardia is often replaced by a pulse rate in proportion to the fever or even higher and the systolic blood pressure drops below 100 mm of mercury. These findings together with evidence of peripheral circulatory failure are bad prognostic signs. Other manifestations of severe disease are signs of involvement of the central nervous system such as delirium, stupor and muscular twitchings. Frank signs of pneumonema may develop.

At the end of the second week the temperature falls by lysis and remains normal after the fourteenth or fifteenth day. With the reduction in fever the pulse rate and blood pressure return to normal levels.

The eschar is practically healed. Convalescence is protracted in patients who fail to receive antimicrobial therapy and full return to mental and physical vigor is usually delayed for several months. Sequelae in the form of nervous or psychiatric disorders and permanent damage to the heart are rare.

**Immunity.** Patients who recover from scrub typhus are resistant to reinfection with the homologous strain of *R. tsutsu gamushi* for some years. However, within two months after recovery, reinfection with a heterologous strain causes mild disease, and after one year, typical scrub typhus. Among the 223 Japanese farmers who gave a history of scrub typhus in the survey mentioned previously, 19 suffered a second attack and 5 had a third attack. The interval between attacks varied from two to forty-four years, with an average of seven years. Convalescent patients exhibit specific neutralizing and complement fixing antibodies. Despite their presence, however, *Rickettsiae tsutsugamushi* persist in the tissues of mice and men for months after clinical recovery.

**Diagnosis.** The geographical distribution of scrub typhus assists in differentiating this disease from other rickettsial infections. Epidemic typhus is absent from the warm regions where most scrub typhus is found. In Southeast Asia, murine typhus (flea borne urban typhus) is the rickettsial infection most apt to be confused with scrub (rural) typhus. The history of recent exposure in town or country, the finding of the scrub typhus eschar, and the results of serological tests during the second and third week serve to differentiate these two diseases. Agglutinins against the OX K strain of *Proteus vulgaris* appear in the serum of patients with scrub typhus and against the OX 19 strain in murine typhus. Finally, negative results with the specific complement fixation tests for epidemic and murine typhus and for spotted fever, and recovery of *Rickettsia tsutsugamushi* from the blood of the scrub typhus patient confirm the diagnosis. The presence in convalescent serum of specific complement fixing antibodies which react with antigens containing *R. tsutsugamushi* is of diagnostic importance. Negative results are of no significance, however, since the antigenic heterogeneity of strains of scrub typhus is such that only a proportion of patients exhibit antibodies which fix complement with the available antigens.

Differentiation of scrub typhus during the first week of illness from typhoid fever, malaria, dengue, infectious hepatitis, leptospirosis, and fevers of unknown origin is

difficult. Headache, conjunctival injection, and lymphadenopathy are more conspicuous in scrub typhus. The eschar and rash, if present, are of some aid, but the early primary lesion may be confused with cutaneous infections which are common in the tropics. The sustained fever in the second week, the development of the black necrotic center in the eschar, and negative results in laboratory tests for typhoid fever and malaria point to scrub typhus. The dramatic improvement within a matter of hours after chloramphenicol or a tetracycline is given to scrub typhus patients is helpful in eliminating most of the nonrickettsial diseases under consideration.

**Prognosis.** Patients with evidence of circulatory failure, encephalitis, or frank pneumonia should be considered gravely affected. Death, when it occurs, usually happens during the second week and is attributable in about equal numbers of cases to the three manifestations just mentioned. The disease is rarely lethal for children, but fatalities increase in proportion to age, and elderly persons usually die. The variations in mortality in different areas have already been discussed.

The prognosis has changed radically since the introduction of chloramphenicol and the tetracyclines in the therapy of this disease. Even the gravely ill and the aged patients now recover under treatment.

**Treatment.** Chloramphenicol and the tetracycline drugs are highly effective in scrub typhus. There is no choice among them, and each is given orally as follows: a "loading dose" of 3 to 4 gm is administered either at one time or over a few hours, and followed by 1 gm amounts at eight-hour intervals until the patient is afebrile. On this regimen, general improvement is evident in twelve hours, and the patients are afebrile in thirty hours on the average. As the temperature becomes normal, headache disappears, appetite returns, and the mental apathy is lost. Critically ill patients may not become permanently fever-free for forty-eight to ninety-six hours.

If treatment is begun within the first few days of disease, a 3 gm supplementary dose of the drug used should be given about the eighth day after onset to prevent relapse, which occurs in about three-fourths of such patients. A supplementary dose is not required in patients who are first treated on the seventh day or later, since immunity in scrub typhus, which begins to develop late in the second week, is adequate in these patients by the time the drug effect is lost. While mild untoward manifestations

not infrequently result from administration of the tetracyclines and chloramphenicol and severe blood dyscrasias may occur very rarely the value of these drugs in scrub typhus is so great and the disease so severe that they should be employed without hesitation

Since the introduction of specific therapy the severe manifestations of scrub typhus are generally brought under control so rapidly that little is needed in the way of supporting therapy. For those in extremis at the time of admission to the hospital paracenteral fluids, transfusions or oxygen therapy may be indicated. Treated patients are now given a full hospital diet within a few days after becoming afebrile and are allowed to sit up a few days later and are usually discharged after a week of normal temperature. They are permitted to return to light work shortly thereafter. Before the introduction of specific treatment military patients were allowed to convalesce from one to four months before being returned to duty.

**Prophylaxis.** Vaccines containing killed *Rickettsia tsutsugamushi* have not been successful in preventing disease in persons exposed under field conditions. It is assumed that the antigenic variations in strains of scrub typhus organisms are mainly responsible for the failure to protect man during field exposure.

**Personal prophylaxis** by avoidance of mites depends primarily on the use of mite repellents and miticidal agents such as dimethyl or dibutyl phthalate or benzyl benzoate. The phthalates are smeared by hand on the clothes and exposed surfaces of the skin (avoiding the eyes and crotch because of the burning sensation produced by the chemical). Impregnation of clothes with benzyl benzoate is attained by dipping the garment in an aqueous emulsion of the substance. When properly used the mite repellents are highly effective in preventing scrub typhus. They are relatively expensive and require constant intelligent use. Short periods of carelessness during exposure in hyperendemic areas result in infection.

Clearing and cultivation of endemic areas of scrub typhus eventually free them of hazard by reducing or destroying the vector mites and rodent reservoirs.

## Rickettsialpox

**Definition.** Rickettsialpox is a mild self limited acute febrile illness caused by *Rickettsia akari* and characterized by an initial skin lesion developing at the site of infection, fever of about one week's duration and a papulovesicular rash.

**History.** Distribution and Epidemiology. Rickettsialpox was first recognized in New York City in 1946 although it undoubtedly existed there earlier. From 140 to 180 cases have been reported annually in New York City since that time. A few cases have been diagnosed in other portions of the United States and outbreaks have been reported in European Russia.

The brilliant work of members of the U S Public Health Service and the New York City Department of Health resulted in isolation of the causal agent from the blood of patients and its identification as a distinct rickettsial species and in the elucidation of the epidemiology of the disease. Rickettsialpox is transmitted by a small colorless mite *Allothromyces sanguineus* (Hirst) which normally infests mice and small rodents. House mice serve as a reservoir of infection. The etiologic agent has been recovered from mice and mites collected from houses in which patients acquired the disease.

**Etiology.** *Rickettsia akari*, the etiologic agent of rickettsialpox, has the general morphological and biological characteristics of other rickettsiae. It is antigenically related to but distinct from *R. rickettsii* which causes Rocky Mountain spotted fever. White mice, guinea pigs and embryonated eggs are susceptible to experimental infection. Diagnostic antigen for use in the complement fixation test with human serum is prepared from yolk sacs of infected chick embryos.

**Morbid Anatomy.** No deaths have been attributed to rickettsialpox; however, skin lesions have been removed surgically for histological examination. The initial lesion of rickettsialpox resembles the primary lesion of scrub typhus. The histopathology of the early maculopapular rash of rickettsialpox consists in changes in the vessels of the corium and perivascular accumulations of mononuclear cells. The vesiculation which develops in the maculopapular lesions of rickettsialpox is unique among the rickettsial diseases. Necrosis of epithelial cells results in an intra epidermal vesicle superimposed on the papule.

FIG 19 Vesicular eruption of rickettsialpox with initial lesion visible on posterior aspect of left thigh (Courtesy of Dr Harry M Rose)

**Symptoms** The period between the bite of the infected mite and the appearance of the initial lesion at this site is from one to two weeks. Three to seven days after the lesion develops the febrile phase begins. The rash may accompany the fever but more frequently appears several days later.

The initial lesion begins as a firm red papule which increases to a diameter of 1 to 1.5 cm. After a few days the center becomes vesiculated; the papule is surrounded by a zone of erythema and the regional lymph nodes are moderately enlarged. The clear vesicular fluid becomes cloudy and dries and a black eschar is formed. The lesion which is not painful heals slowly; the scab drops off about the third week leaving a small scar.

The febrile phase begins with sudden onset of chills or chilly sensations, sweats, headache, muscle pains, anorexia, and photophobia. The temperature frequently reaches 103° to 104° F and remains elevated with morning remissions for approximately one week.

The maculopapular vesicular rash is generalized in distribution and may be abundant or scanty. Lesions occasionally involve the oral mucosa but rarely the palms and soles. The exanthema runs its course in about a week; the vesicles dry and the

scabs fall off leaving a transient discoloration but no scar.

Other findings are essentially limited to those associated with a febrile disease although the spleen is palpable in some cases. Complications are rare.

**Laboratory Findings** The usual laboratory examinations reveal a moderate leukopenia and the findings which are associated with a febrile illness. The erythrocyte sedimentation rate may be slightly elevated.

During convalescence specific complement fixing antibodies which react with antigens containing *Rickettsia alari* appear in the serum of patients. The Weil-Felix test which becomes positive in patients with most rickettsial diseases remains negative in rickettsialpox.

**Diagnosis** Chickenpox has been most frequently confused with rickettsialpox. The following points help to differentiate the two diseases. Rickettsialpox occurs in persons of all ages and has an initial lesion; fever generally precedes the rash; the vesicle surmounts the papule which is discernible throughout the exanthema; and finally diagnosis can be established by a specific serological test. In contrast chickenpox is usually a childhood disease and has no initial lesion; the rash appears at the height of the fever and the papular cutaneous lesion is entirely transformed into a vesicle.

The lesion of the papulovesicular stage of smallpox resembles that of rickettsialpox but the exanthema is generally more abundant in variola. The constitutional reaction in smallpox is greater than in rickettsialpox but it also precedes the rash. Finally the variolar vesicles progress to pustules.

The rashes of the typhus fevers and of the other members of the spotted fever group of the rickettsial diseases are not vesicular; the febrile periods of these diseases are more prolonged than in rickettsialpox and the illnesses are more severe with appreciable mortality rates. The Weil-Felix reaction and specific complement fixation tests using rickettsial antigens are positive. Cross reactions are obtained with serum from patients with Rocky Mountain spotted fever and rickettsialpox when complement fixation tests are used. However if highly purified and washed rickettsial antigens prepared from the two causal rickettsiae are used in the test a definite serological diagnosis can be made.

**Treatment** Symptomatic treatment has been used in this mild self-limiting disease. Dramatic improvement follows the use of chloramphenicol or the tetracyclines.

oral doses of 2 to 4 gm daily render the patient afebrile and essentially free of complaints in forty-eight hours

**Prophylaxis** Control measures consisting in elimination of house mice and vector mites have been attempted in certain of the housing projects in New York City where multiple cases occurred

## Q Fever

**Definition** Q fever is an acute self limited illness characterized by abrupt onset high but somewhat irregular fever head ache and in many instances pneumonitis similar to that of primary atypical pneumonia The first few cases of this disease were called Query fever and from this designation the final name Q fever evolved (Derrick)

**Etiology** Q fever is caused by the micro organism *Coxiella burnetii* which is named for Burnet who first recognized it in Australia and for Cox who described it in the United States *Coxiella burnetii* resembles the other rickettsiae in size shape and staining properties but it differs in certain respects for example it is more resistant to adverse physical and chemical factors than the other rickettsiae An important feature is that *C. burnetii* is the only rickettsial species which infects man without producing a macular or maculopapular rash Further more agglutinins for the *Proteus* group do not appear in human or animal serums as a consequence of infection with *C. burnetii* In the febrile stage of Q fever the micro organisms have been recovered from the blood urine and sputum of patients by appropriate laboratory procedures

**Distribution and Transmission** Q fever has been reported from Australia the United

States Panama Europe the Middle East North and Central Africa possibly India and China It is therefore potentially world wide in distribution The manner in which the disease is usually acquired by man is probably by inhalation of desiccated Q fever rickettsiae derived from various sources

Q fever rickettsiae have been found in the milk of naturally infected cattle sheep and goats in the placentas of cattle and sheep and in the feces of sheep The presence of huge numbers of Q fever rickettsiae in these locations usually is not associated with any evidence of illness of the animal Pasteurization of milk is not completely effective in destroying the viability of Q fever rickettsiae in milk which has been heavily contaminated Furthermore Q fever rickettsiae have been demonstrated in dust laden air at dairies in California Butter made from contaminated milk may contain viable Q fever rickettsiae

In the United States human infections have been reported from many areas particularly California Montana Texas and Illinois Occupational exposure has been related to the occurrence of cases for example in laboratories where the Q fever rickettsiae are cultivated and in dusty environments where wool is processed On the basis of serological tests it is estimated that several thousand persons had Q fever in southern California in recent years The disease is only rarely acquired by contact with patients suffering from Q fever this fact is remarkable in view of the pneumonitis which is a feature of many of the cases It should be noted that *C. burnetii* has been found in certain ticks but that only a few human cases of Q fever have been attributed to contact with infected ticks

**Morbid Anatomy** Few fatal cases of Q fever have been reported and in most of these autopsies were not performed Consequently satisfactory data are not available for general remarks on the pathology of Q fever The reader is referred to the articles by Lillie Perrin and Armstrong and Whittick

**Pathological Physiology and Chemistry** The abnormalities in physiology and chemistry noted in Q fever are those which usually accompany mild fevers of diverse etiology Transient albuminuria and elevated sedimentation rates have been reported The erythrocyte count and concentration of hemoglobin are usually normal and the total leukocyte count is often within

normal limits. Changes in the differential count have been noted but are without diagnostic significance.

**Symptoms and Clinical Course** The incubation period of Q fever is two to three weeks. In several outbreaks the onset occurred abruptly but there are numerous cases in which the disease began insidiously. Malaise, chilly sensations, headache, anorexia and weakness are usually the first symptoms noted. The temperature rises more or less abruptly to 39° C or higher. There are usually wide fluctuations in temperature, particularly if salicylates are administered. The fever persists for a few days in mild cases or it may last for two weeks in severe cases. The pulse rate tends to be somewhat elevated, more or less in proportion to the fever. Generalized muscular aching is frequent. Retro orbital pain is usually noted and is sometimes accompanied by photophobia. In some cases there may be severe and sharply localized pain which either shifts from one site to another or persists for only a few hours.

Toward the end of the first week of illness a dry cough develops in more than half the patients. This may be accompanied by mild to moderate chest pain. In a few patients the cough may become productive of small amounts of sputum, occasionally blood streaked. Despite the cough and chest pain, few patients have symptoms or signs of upper respiratory involvement as part of the Q fever syndrome. The rate of respiration ordinarily is not elevated. Furthermore, physical examination of the chest may reveal nothing to indicate the presence of pneumonia, which is the characteristic feature of Q fever, although fine crepitant rales may reward a careful search. In nearly all cases, however, roentgenographic examination indicates the presence of patchy areas of consolidation involving only small portions of the lobe. A single lesion is the usual finding, but multiple involvement has been noted. Ordinarily the lesions are in the lower lobes, but they may occur in any lobe. It is difficult or impossible to distinguish these findings from those which are present in atypical pneumonia or psittacosis. No correlation has been observed between the extent of pulmonary involvement as judged from the roentgenogram and the severity of the clinical course. The pulmonary lesions sometimes may be found by roentgenogram when the patient is convalescent.

The illness usually ends with complete recovery and the period of convalescence ordinarily is brief, but relapses have oc-

curred in several instances; they are similar to the primary disease and may be mild or severe. The possibility of chronic infection with Q fever has been raised; this question needs careful study. It is probable that there have been many human cases of Q fever so mild as to escape medical attention.

**Diagnosis** The clinical diagnosis of Q fever should be considered when a patient has a febrile illness with anorexia, weakness, severe headache and roentgenographic evidence of a patchy pneumonitis. The absence of symptoms or signs of upper respiratory tract involvement is helpful. The presence of pain in the eyes or of photophobia is a further aid. A prompt response to specific therapy with tetracycline or chloramphenicol may assist the clinical diagnosis. The final diagnosis is usually established by laboratory tests, however, particularly by a rise in titer of complement fixing antibodies in the patient's serum early in convalescence. It is not advisable to attempt isolation of *Coxiella burnetii* from a patient by inoculation of animals, since this procedure usually results in infection among the laboratory personnel. The Weil-Felix reaction and the cold agglutinin test are negative in Q fever.

**Prognosis** The case fatality rate in Q fever is very low. The appropriate use of a tetracycline or chloramphenicol early in the illness should improve the prognosis.

**Treatment** The tetracyclines or chloramphenicol may be used for Q fever. On the basis of present evidence, any of these drugs may be expected to arrest the illness promptly. Relapses may be anticipated if therapy is terminated too soon after the fall in temperature. These agents should be given in the same dosage for Q fever as for Rocky Mountain spotted fever or epidemic typhus (see pp 93-102).

**Prevention** Preventive measures include the pasteurization or boiling of milk from cows, goats and sheep. Vaccination of man with killed suspensions of Q fever rickettsiae affords protection against exposure to infection via the respiratory tract under certain circumstances (Tigerit and Benenson 1956). These writers reported that a single ml of vaccine given early in the incubation period to previously unvaccinated men prevented or delayed the onset of clinical disease. For the infected patient, only one precaution is recommended, namely, the sterilization of sputum and excreta.

## Trench Fever

(Quintan Fever Shin Bone Fever Wol hyman Fever His Werner Disease etc )

**Definition** Trench fever is a specific exanthematic louse born infection characterized usually by a sudden febrile onset with pain and soreness in muscles bones and joints The disease is never fatal

**History** The disease was first recognized in 1915 when it appeared on the Western and Eastern fronts during World War I It constituted one of the major medical problems of World War I and was investigated intensively by a British and by an American commission After demobilization the disease practically disappeared It reappeared during World War II but on a relatively small scale

**Epidemiology and Etiology** The responsibility of the body louse in transmitting the disease to man was established by both British and American commissions as a result of well controlled louse feeding experiments upon human volunteers The infective agent is present in the excreta of lice where it may remain infective for several months The disease is transferable from man to man by intravenous inoculation of blood

As for the etiologic agent there is strong but perhaps not conclusive evidence incriminating an organism (*Rickettsia tulhynica* *R. pediculi* *R. quintana*) the presence of which in the intestines and feces of lice was definitely correlated with infectivity by Bacot Arkwright and Duncan The organism occurs extracellularly in the gut of the louse thus differing from other pathogenic rickettsiae Mosser and Weyer have transmitted the infection to *Phebus* monkeys in which it is subclinical and demonstrable only by the fact that lice fed on infected monkeys become intestinal carriers of the rickettsia No other experimental animal has been shown to be susceptible

**Morbid Anatomy** Postmortem studies have not been made since the disease is never fatal Examinations of excised macules from the skin have apparently shown no important specific changes The spleen is usually enlarged and firm to palpation Rickettsiae have not been satisfactorily demonstrated in human tissues

**Symptoms Incubation Period** Experimental evidence indicates that the usual incubation period ■ ten to twenty days with extreme limits of five to thirty-eight days

**Onset** The onset ■ usually acute with chills and a rise in temperature to 102° or 103° F Severe headache usually behind the eyeballs and complete anorexia are almost constant at this stage Nausea and vomiting sometimes occur Laryngitis and bronchitis may be present but are rarely severe Perhaps the most characteristic symptom is severe "myalgic" pain in various parts of the body but most prominent in the lumbar region and legs There are also muscular soreness pain on rotating the eyeballs conjunctivitis and photophobia Occasionally the onset is insidious with symptoms of neurasthenia and tachycardia

**Course of the Disease** The progress of the disease is remarkably variable The fever and symptoms may last only two or three days or may be typhoidal in character lasting two or three weeks A common form is that in which there are two febrile periods of three to five days each with twelve to twenty four hours of remission between them Again there may be short febrile periods of only twenty four to thirty hours recurring regularly every five days for a variable period of time Relapses are prone to occur several weeks or months after apparent recovery

The characteristic rash usually appears during the first twenty four hours and thereafter comes and goes with fever even in the case of late relapse It is composed of red macules 2 to 10 mm in diameter appearing first on the chest and abdomen and usually confined to those regions although they may involve the entire trunk The extremities are occasionally involved but the face always escapes

The pulse rate during the initial acute attack is increased in proportion to the fever but may be relatively much higher in late relapses A sharp increase in the pulse rate often precedes and may be the only objective evidence of a relapse

Pain and soreness in the muscles usually recur with each febrile relapse Lumbar

pain is most apt to persist in the chronic stage of the disease. Abdominal pain and tenderness probably of muscular origin are usually bilateral and more pronounced on gentle than on firm pressure. This fact together with the palpable spleen, rash and generalized pain and tenderness usually serves to differentiate the condition from appendicitis.

**Prognosis** The disease has no known mortality. Its duration is extraordinarily variable but about 85 per cent of all patients are able to return to work within two months of the time of onset. It is believed that in about 5 per cent of all cases the disease becomes chronic necessitating a much longer period of time for complete recovery. Recovery is apt to be delayed in the aged and in the debilitated.

**Diagnosis** During epidemics typical cases are readily diagnosed on the basis of the symptomatology. The atypical abortive cases may be confused with influenza in the absence of the characteristic rash. The mild respiratory symptoms and the enlarged hard spleen of trench fever are valuable differential criteria in such cases. The typhoidal type is differentiated from true typhoid by the negative Widal reaction and by the almost constant presence of mild to moderate leukocytosis rather than leukopenia. In typhoid, typhus and dengue fever the onset is more gradual than in trench fever and the rash usually appears several days later. Spirochetal relapsing fever and malaria may be excluded by examination of the blood for the specific etiological agents. In cases of the chronic type of trench fever with tachycardia, fatigue, loss of weight and symptoms of neurasthenia the diagnosis may be most difficult. It is theoretically possible to establish strong presumptive evidence of trench fever by feeding carefully controlled lice on such patients and finding that they acquire *Rickettsia uolynica*.

**Treatment** No reliable information is available concerning the value of chloramphenicol and the tetracyclines in trench fever. Pain and discomfort should when ever possible be controlled by such drugs as acetylsalicylic acid and phenacetin rather than by opiates. Codeine is useful in severe pain. Insomnia can usually be controlled by hypnotics. The patient should remain in bed under the best available hygienic and dietary conditions for a week or more after complete cessation of subjective and objective evidence of infection. He should be kept under observation for several months and returned to bed at the first sign of relapse.

**Prophylaxis** Prevention of the disease is largely a question of efficient delousing by the chemical techniques developed during World War II (see Typhus Fever page 93). Destruction of the infective agent on clothing contaminated by louse excreta is also of primary importance. Autoclaving is probably the most satisfactory method. Disinfection of urine and sputum may be carried out by chemical methods or by heat. Louse proof garments and rubber gloves should be worn by those attending patients or handling clothing. Trench fever patients are best treated in separate wards.

## BACTERIAL DISEASES

### Pneumonia

#### Pneumococcal Pneumonia

**Definition** Pneumococcal pneumonia is an acute bacterial infection of the lungs caused by pneumococcus and characterized clinically by an abrupt onset with chills fever chest pain cough and bloody sputum

**History** Although pneumonia was known to Hippocrates its usual cause was not learned until late in the nineteenth century. *Pneumococcus* was first isolated from normal saliva in 1881 by Pasteur and by Sternberg. Several years later its causative role in pneumonia was demonstrated independently by Frankel and Weichselbaum. Identification of different serological types of pneumococci which began with the studies of Neufeld in Germany and Dochez in this country led eventually to serum therapy and to the highly significant observations of Avery, Enders, Heidelberger and Goebels concerning the chemical nature of the capsular antigen and its relation to pathogenicity. In 1928 Griffith demonstrated that pneumococci of one type may be transformed into pneumococcal cells of another type. This remarkable transforming reaction, the epidemiological and genetic implications of which are of great importance, has been shown by Avery and his collaborators to depend upon a highly polymerized deoxyribonucleic acid of the bacterial cell. Present concepts of the pathogenesis of pneumococcal pneumonia derive from the systematic histological investigations of Robertson and Loeschcke. The seriousness of the disease in man was drastically modified by the advent of sulfonamide therapy in the late 1930's and more recently treatment has been further improved by the introduction of penicillin and other antimicrobial drugs.

**Bacteriology and Immunology** More than 95 per cent of all primary bacterial pneumonias are caused by pneumococci. The somatic portion of the lancet shaped pneumococcal cell is gram positive. In its virulent form pneumococcus has an outer capsule consisting of a loosely packed gel containing a high molecular polysaccharide polymer which is specific for each serological type. In addition to the type specific capsular antigen there is in the somatic portion a species specific carbohydrate known as the "C" substance. A nontype specific protein antigen can also be demon-

strated in the somatic portion of the cell and recently Austrian and MacLeod have identified a type specific protein analogous to the M substance of beta hemolytic streptococci. The capsule of pneumococcus acts as an armor against phagocytic cells and thus contributes significantly to the pathogenicity of the organism. Pneumococcal variants having no capsules (rough or R strains) are essentially avirulent. Antibody to the type specific carbohydrate promotes phagocytosis by combining with the highly polymerized polysaccharide of the capsular gel. Antibodies to the other antigens appear to have relatively little effect upon the invasive properties of the organism. The pneumococcal cell also produces hyaluronidase, a pneumolysin which causes hemolysis in blood agar and autolytic ferment which in time destroy the gram complex and eventually cause dissolution of the cell itself.

Pneumococci can be grown on a variety of bacteriological media. Blood agar and beef infusion broth containing 0.5 per cent dextrose and 5 to 10 per cent blood or serum are the mediums most commonly used. The pH of the medium should be approximately 7.5. In a suitable broth the organism grows rapidly and on blood agar virulent (smooth S) strains form circular glistening dome shaped colonies which are alpha hemolytic. Because of the great quantity of capsular polysaccharide formed by type III pneumococcus its colonies are more mucoid and usually about twice as large (2 mm in diameter) as those of other types. Unlike the alpha hemolytic streptococcus pneumococcus is soluble in bile, sodium desoxycholate and other surface active agents, is highly sensitive to optochin and is mouse virulent. Most strains are virulent for mice, rats, rabbits, dogs and monkeys as well as for man.

The extraordinary virulence of pneumococci for mice is made use of in isolating the organisms from sputum. The technique usually used consists in injecting intra-

pain is most apt to persist in the chronic stage of the disease. Abdominal pain and tenderness probably of muscular origin are usually bilateral and more pronounced on gentle than on firm pressure. This fact together with the palpable spleen rash and generalized pain and tenderness usually serves to differentiate the condition from appendicitis.

**Prognosis** The disease has no known mortality. Its duration is extraordinarily variable but about 85 per cent of all patients are able to return to work within two months of the time of onset. It is believed that in about 5 per cent of all cases the disease becomes chronic necessitating a much longer period of time for complete recovery. Recovery is apt to be delayed in the aged and in the debilitated.

**Diagnosis** During epidemics typical cases are readily diagnosed on the basis of the symptomatology. The atypical abortive cases may be confused with influenza in the absence of the characteristic rash. The mild respiratory symptoms and the enlarged hard spleen of trench fever are valuable differential criteria in such cases. The typhoidal type is differentiated from true typhoid by the negative Widal reaction and by the almost constant presence of mild to moderate leukocytosis rather than leukopenia. In typhoid typhus and dengue fever the onset is more gradual than in trench fever and the rash usually appears several days later. Spirochetal relapsing fever and malaria may be excluded by examination of the blood for the specific etiological agents. In cases of the chronic type of trench fever with tachycardia fatigue loss of weight and symptoms of neurasthenia the diagnosis may be most difficult. It is theoretically possible to establish strong presumptive evidence of trench fever by feeding carefully controlled lice on such patients and finding that they acquire *Rickettsia uolhynica*.

**Treatment** No reliable information is available concerning the value of chloramphenicol and the tetracyclines in trench fever. Pain and discomfort should when ever possible be controlled by such drugs as acetylsalicylic acid and phenacetin rather than by opiates. Codeine is useful in severe pain. Insomnia can usually be controlled by hypnotics. The patient should remain in bed under the best available hygienic and dietary conditions for a week or more after complete cessation of subjective and objective evidence of infection. He should be kept under observation for several months and returned to bed at the first sign of relapse.

**Prophylaxis** Prevention of the disease is largely a question of efficient delousing by the chemical techniques developed during World War II (see Typhus Fever page 93). Destruction of the infective agent on clothing contaminated by louse excreta is also of primary importance. Autoclaving is probably the most satisfactory method. Disinfection of urine and sputum may be carried out by chemical methods or by heat. Louse proof garments and rubber gloves should be worn by those attending patients or handling clothing. Trench fever patients are best treated in separate wards.

toward the pharynx (at a rate of 1 to 3 cm per hour) (1) the cough reflex which serves to propel the mucus out of the lower tract (5) the lymphatics which drain the terminal bronchi and bronchioles and (6) the mononuclear phagocytes (dust cells) which are ever present in the normal alveoli. In addition the alveoli themselves are relatively dry and thus offer a poor medium for growth to the few bacteria that succeed in reaching them. Only when the defense barriers of the normal respiratory tract are disturbed does acute bacterial pneumonia result.

The thesis that bacterial pneumonia frequently results from aspiration of infected secretions from the upper respiratory tract is strongly supported by both experimental and clinical observations. Rats infected with pneumococci in the nasopharynx regularly exhibit pulmonary lesions only when subjected to experimental procedures involving chilling of the body, anesthesia, administration of morphine and alcoholic intoxication, all of which are common predisposing factors in human pneumonia and have been shown in the experimental animal to slow the epiglottal reflex and thus to facilitate aspiration. Experimental pneumonia can best be produced by intrabronchial inoculation of organisms suspended in mixtures of gastric mucin or starch having viscosities similar to that of mucus. Viral infection of the upper respiratory tract in man usually precedes the onset of acute bacterial pneumonia by several days. Not only is the volume of secretion from the nasopharynx greater than normal during viral infections such as the common cold, but also the number of pathogenic microorganisms in the secretions is significantly increased. Thus the stage is set for aspiration of infected mucus. That such aspiration often occurs at the onset of human pneumonia is suggested by the usual sites of initial involvement of the lung. The earliest lesions of bacterial pneumonia usually appear in those parts of the lungs into which aspirated fluid is most likely to drain. Whereas most air-borne bacteria are caught on the sticky surfaces of the bronchial tree and never reach the alveoli, organisms contained in thin nasopharyngeal secretions are readily carried into the alveoli by the liquid mucus. The latter, like Lipiodol, cannot all be ejected by ciliary action and much of it penetrates to the farthest reaches of the bronchial tree where it establishes the initial focus of infection.

Other factors known to predispose patients to acute bacterial pneumonia include

exposure to noxious gases and anesthetics, cardiac failure, influenzal virus infection of lungs, trauma to the thorax and pulmonary stasis resulting from prolonged bed rest. A feature common to all these conditions is the accumulation of fluid in the alveoli. Harford has shown that the dry lungs of normal mice are able to rid themselves of large numbers of inspired bacteria, whereas lungs containing fluid are readily infected. This observation suggests that pulmonary edema, by providing a suitable culture medium for the bacteria, may facilitate the establishment of active infection within the alveoli.

**Early Lesion.** Once the infection has gained a foothold within the alveoli, the lesion evolves in a characteristic manner. The first response of the lung to bacterial invasion is an outpouring of edema fluid into the alveoli. This serous fluid not only serves as a suitable culture medium for the organisms but also floats them into new alveoli through the pores of Cohn and terminal bronchioles (Fig 20 a). Centrifugal spread of the alveolar fluid is enhanced by motion of the pulmonary parenchyma caused by respiration and cough. After the outpouring of edema fluid, polymorphonuclear leukocytes and some erythrocytes accumulate in the infected alveoli first in small numbers (Fig 20 b) but later in such quantities as to fill each alveolus and thus render the area completely consolidated (Fig 20 c). Once the infected alveoli become crowded with leukocytes, phagocytosis of bacteria takes place and the invading organisms are destroyed. Macrophages appear in the exudate and resolution begins only after most of the organisms have been ingested. The macrophages which accomplish the final clearing of cellular debris from the resolving lesion appear to be derived both from monocytes of the blood and from the septal cells of the alveolar walls which become characteristically thickened during the process of resolution (Fig 20 d).

**Spreading Lesion.** These stages in the inflammatory reaction account for the distinguishing histological features of the spreading pneumonic lesion. In the outermost portion there appears an edema zone in which the alveoli are filled with acellular serous fluid containing many bacteria. Inside the edema zone a second zone may be identified in which there are signs of early consolidation with leukocytes in most of the alveoli. Here phagocytosis is often noted. Still more centrally a third transition to a zone of advanced consolidation is noted where the alveoli are packed with cells and

peritoneally 0.5 cc of sputum previously emulsified by having been drawn repeatedly into a tuberculin syringe. When virulent pneumococci are present the mouse dies within forty-eight hours and a pure culture of the organism can be isolated from the heart's blood. Since other bacteria in the sputum do not ordinarily produce fatal infections in mice the animal serves as a convenient and highly sensitive differential culture medium for the isolation of pneumococci. The mouse inoculation technique however cannot be relied upon in recovering type XIV pneumococcus for this organism the capsular polysaccharide of which is immunologically related to blood group A substance is not mouse virulent.

More than seventy-five different serological types of pneumococci have been identified. Typing may be done by agglutination tests with specific antisera or by the quellung test. The latter is based upon the characteristic capsular "swelling" (quellung) caused by homologous type-specific antibody. Tests used for the identification of type-specific antibody in sera and other body fluids include in addition to the agglutination and quellung methods mouse protection tests, precipitin reactions and opsonocytaphagic and bactericidal tests.

Antibody usually appears in the blood of patients with pneumococcal pneumonia between the fifth and tenth days of the disease. The presence of a significant quantity of antibody in the blood can be demonstrated by the cutaneous reaction resulting from the intracutaneous injection of homologous capsular antigen (Francis skin test). In some untreated patients the appearance of circulating antibody may coincide with recovery but in others no relation can be demonstrated between the crisis and the existence of humoral immunity. In severe pneumococcal infections specific polysaccharide which has diffused away from the multiplying bacteria can often be identified by precipitin test in the urine and sometimes can even be detected in the blood. Patients frequently continue to excrete the capsular carbohydrate in the urine for days and even weeks after recovery.

**Epidemiology.** Pneumococcal pneumonia may occur at any season but is most common during the winter and early spring when respiratory infections in general are most prevalent. The high incidence of the disease in winter and spring is undoubtedly due to the fact that acute bacterial pneumonia is usually secondary to injury of the respiratory mucosa by viral infec-

tions such as influenza and the common cold.

The types of pneumococci that most commonly cause pneumonia in adults are types I, III, VII, II, VIII, IV, XI, X, XIV and XIV. In the order listed. Together these ten types account for three quarters of all cases. Type XIV is particularly common in childhood infections. Other types are occasionally isolated from pneumonic sputum but their comparative rarity suggests that they are of less virulence for man than the more commonly encountered types.

Pneumococci particularly of the higher types are frequently present in the respiratory tracts of normal subjects. Ordinarily the prevalence of carriers of highly pathogenic types such as I and II is relatively low except for type III which is a common inhabitant of the normal pharynx. Nevertheless there is evidence that normal carriers play a more important role in the dissemination of infective types than do patients ill with pneumonia. Occasionally in relatively closed communities high carrier rates of pathogenic types are encountered. In such circumstances the occurrence of widespread viral disease of the respiratory tract may result in an epidemic of pneumococcal pneumonia. Except for these rare epidemics most of which occur in hospitals or custodial institutions the disease is sporadic.

Pneumococcal pneumonia is slightly more common in Negroes than in whites and is particularly frequent among workers in steel mills and coal mines. It may occur at any age but is of highest incidence in the second, third and fourth decades. The ratio of male to female patients is approximately three to two, the difference probably being due to occupational factors involving frequency of exposure.

**Pathogenesis and Morbid Anatomy.** The lung is the only major viscus of the body exposed to the air. Since the atmosphere particularly in congested places contains many bacteria it is remarkable that pneumonia is not an almost universal disease. The failure of normal subjects to acquire acute bacterial pneumonia as an air-borne infection is due to the extraordinarily efficient defense barriers of the lower respiratory tract. These defenses include (1) the epiglottis reflex which prevents gross aspiration of infected secretions from the pharynx, (2) the sticky mucus which lines the bronchial tree and to which air-borne organisms adhere, (3) the cilia of the respiratory epithelium which keep the infected mucus moving constantly upward.

where beginning resolution may be evident. In the central zone of advanced consolidation fibrin is often noted in the alveolar exudate, the large fibrinogen molecules having passed through the injured walls of the alveolar capillaries along with erythrocytes.

From the foregoing description it is clear that all stages of inflammation can be found in a spreading lesion. In the most recently invaded areas at the periphery edema and hemorrhage predominate, causing red hepatization; whereas in the older, more central parts of the lesion dense consolidation with leukocytes accounts for the characteristic color of "gray hepatization." Only if the infection has stopped spreading hours before necropsy will the entire lesion be in the stage of gray hepatization. Thus the spread of pneumococcal pneumonia may be likened to that of a grass fire where the flames, having spread centrifugally, are concentrated at the periphery, leaving behind a charred and burned-out center.

Not all pneumococcal pneumonia causes lobar consolidation. Less malignant lesions may be patchy in distribution and concentrated particularly about the bronchi. Since a clear-cut distinction between pneumococcal bronchopneumonia and lobar pneumonia cannot always be made even by the pathologist and since management of the two conditions is essentially the same, it is rarely important for the clinician to differentiate them. The etiology rather than the anatomy of the lesion determines therapy.

**Interlobar Spread.** If the pneumonic process has involved all the parenchyma of a single lobe, its spread may be stopped by the pleural boundaries of the lobe and spontaneous recovery may then ensue. Often, however, the infection spreads to other lobes of the lungs. Interlobar spread has been shown in experimental pneumonia to result from the flow of infected edema fluid (Fig. 20 e) from bronchi of the involved lung into the bronchial tree of a new lobe. Spread to a given lobe may be brought about by suspending the infected animal in such a way that gravity will carry the bronchial fluid into the desired lobe. It may be assumed that a similar mechanism operates in human patients with multilobar lesions. The fact that the commonest spread in human pneumonia is from one lower lobe to another is in keeping with the assumption that organisms are carried to the new lobe by infected bronchial fluid, the flow of which is influenced by cough, respiration and the force of gravity.

**Bacteremia.** Bacteremia frequently occurs during the course of pneumococcal pneumonia, particularly when the infection is fulminating. The fact that organisms appear in the thoracic duct in experimental pneumonia before they appear in the systemic circulation suggests that many of the organisms reach the blood stream via the lymphatics. It is well known that particles introduced experimentally into the alveoli are cleared primarily by lymphatic drainage. At least some of the bacteria in the spreading lesion appear to be removed from the lung by a similar mechanism. Their presence in regional mediastinal lymph nodes during experimental pneumonia has been repeatedly demonstrated. Whether bacteria gain access to the blood stream by penetrating the alveolar capillaries directly is not known.

**Invasion of Pleura and Pericardium.** The exact mechanism whereby pneumococci invade the pleura or pericardium is also unknown. Since the lymphatics at the periphery of the lung drain outward toward the pleura, it is possible that pleural invasion results from lymphangitic spread. On the other hand, it is also possible that organisms are carried through the visceral pleura along with edema fluid which accumulates in infected subpleural alveoli. When infection of a pleural or pericardial cavity occurs, there results an outpouring of serous fluid followed by the deposit of fibrin. Later leukocytes accumulate in the infected cavity and if infection persists a purulent focus results. The pus in such cavities is at first thin but later becomes thick and stringy as a result not only of fibrin formation but also of the precipitation of desoxyribonucleic acid derived from the nuclei of disintegrating leukocytes. Finally the thick fibrinous pus becomes walled off, forming loculated foci of chronic suppuration.

Similar purulent foci may occur in the meninges or joints, probably as a result of hematogenous metastasis. Acute vegetations on the endocardium of the heart valves are sometimes encountered and acute splenic tumor indicative of systemic infection is a common finding in fatal cases observed at necropsy. Degeneration of renal tubules is also occasionally noted and since identical changes can be produced in the kidneys of laboratory animals by repeated injections of killed pneumococci, the lesions are assumed to be of pneumococcal origin.

**Mechanism of Recovery.** Surface phagocytosis. Because of the antiphagocytic properties of their capsules, virulent fully en-

FIG 20 a Pneumococci in edema filled alveoli at margin of spreading pneumonic lesion ( $\times 800$ )

 i Cell has trapped some of the encapsulated bacteria against the wall and is in the process of phagocytosing them Time 12 32  
 j Having ingested several of the organisms the leukocyte is moving up the alveolar wall Time 12 35 (Photomicrographs from studies on experimental pneumonia W B Wood *et al* J Exper Med Vol 73 and Smith and Wood *ibid* Vol 86)

layer" which interferes with surface phagocytosis and accounts at least in part for its extraordinary pathogenicity. Type III pneumococci may accumulate in huge numbers in infected alveoli and on occasion cause necrosis not only of leukocytes but also of the alveolar walls. If the necrosis is sufficiently widespread, chronic lung abscesses result.

**Suppurative Extrapulmonary Foci.** Suppurative pneumococcal lesions which usually occur in such extrapulmonary sites as the pleura, pericardium, mastoids, or accessory sinuses, resolve much less readily, even with intensive chemotherapy, than does uncomplicated pneumococcal pneumonia. In such areas of suppuration, phagocytosis is relatively inefficient, first because of the fluid present in the lesion, secondly because of the absence of such extensive tissue surfaces as are afforded by the alveoli of the lung, and thirdly because many, if not most, of the leukocytes in the exudate are nonviable. In addition, chemotherapeutic agents administered systemically probably do not penetrate subacute or chronic suppurating lesions as readily as they do areas of acute pneumonia. Even when a drug such as penicillin reaches the organisms in a purulent focus, it may not necessarily destroy them. Pneumococci do not multiply rapidly in pus of long standing, and it is well known that "resting" bacteria are not susceptible to the antibacterial action of penicillin. Thus it is not surprising that clinical experience has demonstrated that purulent pneumococcal infections, such as an empyema, respond satisfactorily only when chemotherapy is combined with some form of drainage which removes the bulk of the necrotic exudate.

**Symptoms.** Victims of pneumococcal pneumonia are often seriously ill when first seen. The degree of prostration may be such that an adequate history can be obtained only from the family or some other close associate of the patient. The story of a mild nasopharyngitis preceding by several days the onset of major symptoms is frequently elicited by careful questioning. The first distressing symptom is usually a *shaking chill* lasting for several minutes to a half hour. More than 80 per cent of patients with pneumococcal pneumonia experience one or more chills during the earliest stages of the disease. The initial rigor is often so violent as to cause the bed to shake and the patient's teeth to chatter. It is followed in about one case in three by vomiting. The exact cause of

the initial chill is not known, but it usually coincides with bacterial invasion of the lung and marks the onset of fever. Several chills may occur at the start of pneumococcal pneumonia, but repeated attacks of rigor late in the disease suggest an extrapulmonary complication such as endocarditis or empyema.

**Chest Pain.** In approximately 70 per cent of cases, severe chest pain occurs at the onset and may even precede the rigor. The pain, which is "stabbing" in character and is exaggerated by cough and respiration, is caused by inflammation of the pleura resulting from the characteristically peripheral location of the initial lesion. There may be local tenderness in the chest wall at the site of the pleurisy. When the diaphragmatic surfaces of the pleura are affected, the pain is referred either to the corresponding side of the abdomen or to the shoulder, depending upon whether the peripheral (intercostal innervation) or central (phrenic innervation) part of the diaphragm is involved. The patient may gain some relief from the knife-like pain by lying on the affected side, thereby partially splinting that half of the thorax.

**Cough** may be absent at the onset but usually is a prominent symptom during the course of the disease. Stimulation of the cough reflex results from irritation of the lower respiratory tract and from accumulation of mucus and exudate within the bronchial tree. Approximately 75 per cent of patients raise diffusely bloody or "rusty" sputum in contrast to "blood-streaked" sputum. The thorough mixing of the blood and mucus appears to be due to the fact that bleeding occurs directly into the alveolar exudate and thus constitutes an integral part of the inflammatory response to the infection. When the sputum is particularly sticky or jelly-like, type III pneumococcus or Friedlander's bacillus should be suspected as the cause of the pneumonia, since both these organisms produce, during growth, an inordinate amount of capsular polysaccharide which causes the exudate to be highly viscous.

**Fever and toxicity** are constant features of the disease; the temperature usually ranging between 103 and 106 F. During the febrile period, complaints of malaise, weakness, myalgia, and general prostration are extremely common.

**Physical Signs.** Since pneumococcal pneumonia may occasionally progress with great rapidity and the general condition of the patient may deteriorate alarmingly within

capsulated pneumococci are resistant to phagocytosis when suspended in a fluid medium as in ordinary opsonocytaphagic tests performed in the laboratory. Such is not the case however within consolidated lesions *in vivo* where phagocytosis of fully encapsulated bacteria readily occurs. This important difference in phagocytic efficiency has been shown to be due to the presence in tissues of suitable surfaces against which the leukocytes are able to trap the encapsulated organisms and thus ingest them without the aid of opsonizing antibody (see Fig 20 p 116). The efficiency of this surface phagocytosis which operates also within the interstices of fibrin clots depends in large measure upon the amount of fluid present in the lesion. In the outer edema zone where fluid is abundant and leukocytes relatively scarce little phagocytosis occurs. In areas of more advanced consolidation however where actively motile leukocytes are packed closely together the bacteria are not only effectively trapped against tissue surfaces and fibrin strands within the exudate but are also caught between the surfaces of the phagocytic cells themselves and are thus ingested. This efficient mechanism of natural defense operating in the absence of immune bodies explains the prompt destruction of bacteria which is characteristic of the central portions of even the spreading pneumonic lesion. Studies on experimental bacteremia have also shown that surface phagocytosis plays an important role in disposing of pneumococci which have invaded the blood stream.

Likewise when spread of the lesion is controlled by antimicrobial drugs such as penicillin surface phagocytosis promptly disposes of the bacteria that are not destroyed outright by the drug or by autolysis. Consequently it is not surprising that with adequate chemotherapy experimental pneumococcal lesions may clear completely and patients with pneumococcal pneumonia may experience dramatic defervescence many hours before opsonizing immune bodies can be detected in either the serum or the lesion. When a patient is treated sufficiently late in the course of the disease antibody may be present in the serum and may then contribute to recovery by accelerating phagocytosis.

**Macrophage Reaction** The exact role of the macrophage reaction in the recovery process is not entirely clear. Because the appearance of macrophages in the alveolar exudate coincides in general with the disappearance of organisms from the lesion

it has long been assumed that these large mononuclear phagocytes take an active part in destroying the bacteria and in the final analysis tip the scales in favor of the cellular defenses of the host. Studies relating to experimental lymphadenitis cast some doubt upon this assumption. The macrophage reaction in a regional lymph node draining an area of active infection can be artificially initiated at any stage of the nodal inflammation by merely cutting the afferent lymph vessels bringing bacteria to the node. Thus it appears that macrophages accumulate in the exudate only when the active stimulus of direct bacterial invasion has been eliminated. If this interpretation is correct the polymorphonuclear leukocytes may be looked upon as the "shock troops" that play the major role in controlling the infection whereas the macrophages serve primarily to remove the particulate debris from the resolving exudate and thus promote clearing of the lesion.

**Resolution** One of the most remarkable features of pneumococcal pneumonia is the completeness with which it resolves. Even when several lobes are completely consolidated at the height of the illness recovery usually results in restoration of the entire pulmonary parenchyma to its normal state within a few weeks. Not all the processes that take part in this dramatic resolution have been identified but they appear to include (a) the action of cytolytic ferments upon disintegrating leukocytes, (b) increased acidity of the exudate, (c) transport of cells from the lesion via lymphatics and (d) phagocytosis and digestion of cellular debris by macrophages. The rarity with which tissue necrosis occurs in pneumococcal pneumonia despite the violence of the inflammatory response appears to account for the completeness of the healing. Occasionally recovery proceeds more slowly than usual and leads to delayed resolution. The factors responsible for delaying the removal of exudate from the lesion in such cases are not known. In rare instances as the result of irreversible damage to the pulmonary parenchyma resolution fails to take place altogether and the lesion becomes the site of intense fibroblastic activity which leads to the permanent scarring of organized pneumonia.

Although resolution is usually complete in pneumococcal pneumonia infection with type III pneumococcus may occasionally lead to pulmonary suppuration. This particular type of pneumococcus in its most virulent form has a large capsular "slime

parietal pleura over the outer part of the diaphragm. The right upper quadrant should always be carefully examined for signs of enlargement or tenderness of the liver resulting from congestive heart failure.

In addition to edema from heart failure the most important physical signs encoun-

tered in the extremities are those of phlebotrombosis. Since pulmonary infarction may closely resemble acute bacterial pneumonia it is of the utmost importance to look for evidence of venous thrombosis in the legs.

The neurological examination is rarely

FIG 21 a Postero-anterior roentgenogram of chest of fifty year-old man with pneumococcal type VI pneumonia of five days duration. Note narrowed intercostal spaces on right and increased density in right lower lung field. Such a pulmonary shadow might be due to pneumonia in either the middle (anterior) or the lower (posterior) lobe or in both.

b Lateral view reveals that consolidation is confined to middle lobe except for a few small patches in the lower. The sharpness and density of the upper border of the middle lobe shadow suggest the presence of a pleural effusion in the interlobar fissure between the upper and middle lobes. Sterile pleural fluid was obtained from the interlobar space by thoracentesis. The patient recovered promptly with penicillin therapy.

c Loculated postpneumonic empyema in a forty year-old white man admitted to the Bellevue Hospital, New York, on the nineteenth day of pneumococcal pneumonia. Only 50 ml of thick greenish pus could be removed from the right chest by aspiration. Cultures were sterile. Pleural loculations are visible in the roentgenogram. Ten milliliters of a preparation containing 100 000 units of streptokinase and 25 units of streptodornase were introduced through the thoracentesis needle. Twenty four hours later 465 ml of cloudy thin blood tinged fluid were removed.

d Roentgenogram taken after the second thoracentesis performed twenty four hours after enzyme treatment. Temperature fell to normal and patient made a rapid recovery. No further aspirations were necessary.

a few hours it is essential that the initial physical examination be as thorough as possible

The temperature pulse rate and respiratory rate are usually elevated by the time the patient seeks the aid of a physician. The temperature should be taken by rectum since oral measurement with the subject breathing rapidly through the mouth is likely to be inaccurate. The pulse pressure is characteristically widened as in any high fever and the pulse at the wrist may be collapsing in quality. Subnormal blood pressure indicates shock and a poor prognosis.

Patients with well established pneumococcal pneumonia appear acutely ill. There is moderate to severe respiratory distress. The nostrils dilate with each inspiration. Paroxysms of hacking cough often productive of bloody or rusty sputum occur during the examination. The chest pain which is usually unilateral may be so severe as to interfere with the patient's breathing and coughing in these circumstances grunting expiration results. The location of the pain indicates immediately the approximate site of at least part of the lesion. The patient occasionally appears apprehensive and may even be delirious.

The skin is usually hot and moist with beads of perspiration visible on the face and forehead. Cold extremities may indicate impending shock. Herpetic blisters are frequently noted about the mouth. The lips, mucous membranes and nail beds are often cyanotic as a result of blood passing through involved lung. The cyanosis may be exaggerated by poor respiratory exchange caused by severe pleural pain. Icterus of the sclerae should be carefully looked for because of the prognostic significance of overt jaundice in pneumonia. Occasionally petechiae are found in the skin of patients suffering from complicating pneumococcal endocarditis.

The ears should always be examined with an otoscope to exclude the presence of active otitis. Tenderness over a mastoid process or over an accessory nasal sinus should also be noted. The presence of exudate in the pharynx or over the tonsils suggests the possibility of streptococcal pneumonia. Definite nuchal rigidity is usually indicative of pneumococcal meningitis, a serious and not too infrequent complication of pneumonia. The neck veins must be carefully examined to detect the presence of increased venous pressure caused by complicating congestive heart failure. Deviation of the trachea constitutes an important sign of either atelectasis (toward the in-

volved side) or pleural effusion (away from the involved side).

**Examination of the Chest** The thorax must be examined with the utmost care. Diminished respiratory excursion or a slight inspiratory lag of one side of the chest often reveals the site of the principal lesion. A localized area of tenderness in the chest wall noted during percussion may be one of the earliest signs of pleural invasion. The presence of a large pleural effusion sometimes causes a noticeable fullness of intercostal spaces. Careful percussion and auscultation do not invariably reveal signs of consolidation. In early cases particularly there may be no conclusive physical signs. Lesions at a distance from the chest wall are difficult to outline by percussion. Breath sounds may be only slightly depressed if normal lung tissue separates the lesion from the large bronchi. When consolidation is extensive the typical findings of dullness to percussion, bronchial or tubular breath sounds and fine crackling rales are easily elicited except in the presence of complicating bronchial obstruction or extensive pleural effusion. A coarse "leathery" friction rub is frequently audible in the region of consolidation.

Examination of the heart may be difficult because of loud respiratory sounds. Its position and size should be carefully determined by palpation and percussion. A later shift in the position of the left cardiac border may indicate any one of the following complications: cardiac enlargement from heart failure, invasion of the pericardial cavity, atelectasis or pleural effusion. An apical systolic murmur is frequently heard during high fever and is often of no significance although it may be due to bacterial vegetation. Diastolic murmurs on the other hand arising from either the mitral or aortic valve are usually indicative of underlying organic heart disease or complicating pneumococcal endocarditis. A pericardial friction rub often constitutes the first sign of spread of the pneumococcal infection to the pericardial cavity. Ventricular premature contractions are not uncommon in the presence of any moderate or severe infection.

**Abdominal Distention** Distention of the abdomen is frequently encountered in advanced bacterial pneumonia. Its presence is due to paralytic ileus. Occasionally the examiner will note rigidity and even tenderness in one or both upper quadrants of the abdomen suggesting a subdiaphragmatic lesion. This sign is usually due to referred pain resulting from involvement of the

slight secondary rise in temperature occurs after the crisis and low grade fever may persist during the first few days of recovery. Not only does defervescence occur promptly after effective therapy but the patient experiences striking relief of symptoms and exhibits a marked improvement in general appearance. Physical signs in the chest also change within a few days: coarse sticky rales of resolution replacing the fine crepitant rales and tubular breath sounds of consolidation. Complete clearing of the pulmonary lesion may occur within a few days but usually the auscultatory signs of resolution persist for a week or more after defervescence. If resolution is not complete within twenty-one days it is arbitrarily classified as delayed. The promptness of defervescence and the speed of resolution are in general inversely proportional to the age and extent of the lesion at the time treatment is begun.

Crisis marking the start of recovery must be differentiated from the "pseudocrisis" occasionally noted at the onset of peripheral vascular collapse or at the time of interlobar spread of the infection. Although the temperature may fall precipitously during a pseudocrisis the pulse rate remains elevated and the patient's general condition fails to improve.

Relapse may occur in pneumococcal pneumonia, particularly when chemotherapy is discontinued too soon. If fever, tachycardia and other signs of active infection recur while the patient is still receiving intensive penicillin therapy it may usually be assumed that a previously unrecognized purulent complication of the pneumococcal infection (such as empyema) exists that a drug resistant secondary invader has gained a foothold in the lung or that hypersensitivity of the patient to penicillin has caused the development of drug fever.

**Complications.** The commonest specific complication of pneumococcal pneumonia is pleurisy with effusion. In somewhat less than 10 per cent of cases fluid can be demonstrated in the pleural cavity by either physical or roentgenographic examination. Such effusions are usually small and when sterile are rarely of significance. They result from inflammation of the pleura overlying the parenchymal lesion of the lung. Occasionally they may be of sufficient volume to cause respiratory embarrassment and necessitate thoracentesis. Whenever pleural effusion is detected in a patient who has failed to respond promptly to treatment a thoracentesis should be performed

in order to determine whether the fluid is infected and is thus in effect an empyema. Samples of the fluid obtained should be examined directly with bacterial stains inoculated intraperitoneally into a mouse and cultured both aerobically and anaerobically.

**Empyema.** Empyema though less common than sterile pleural effusion is far more serious. Before the advent of chemotherapy the incidence of this complication was approximately 5 per cent. With the present widespread use of penicillin empyema is much less common (under 2 per cent). Its presence is indicated by continued fever (often irregular), persistent leukocytosis, repeated sweats and signs of pleural effusion (Fig 21 c). Localized tenderness is frequently noted in the chest wall overlying the site of the lesion. The exudate in the pleural cavity may become loculated by thick fibrinous adhesions. If it is present in sufficient quantity it may cause fullness of intercostal spaces and a shift of the trachea and mediastinum away from the side of the lesion. When the lesion is confined to an interlobar fissure or located in the thoracic "gutter" adjacent to the spine it may be detectable only by roentgenographic methods. Repeated exploratory thoracenteses may be required to prove the presence of empyema. Its detection is of the greatest importance since once discovered it is amenable to proper therapy whereas if left untreated it may eventually drain exteriorly through the chest wall (empyema necessitatis) or rupture into a bronchus and cause a bronchopleural fistula. Rarely empyema heals spontaneously causing calcification of the pleura. The fluid contained within an empyema cavity is at first thin but soon becomes so thick and stringy that aspiration through a needle is difficult. The solid material within the pus is composed not only of fibrin but also of desoxyribonucleic acid derived principally from the nuclei of disintegrating leukocytes. Tillett has shown that both these solid components can be dissolved by enzymes (streptokinase and streptodornase) derived from beta hemolytic streptococci. As indicated under Treatment this discovery has led to an important advance in the therapy. The initial sample of exudate obtained by thoracentesis should always be subjected to bacteriological study (see under Pleural Effusion) since identification of the offending organism is essential for proper treatment.

**Meningitis and Endocarditis.** Two serious but now comparatively rare complica-

abnormal in pneumococcal pneumonia except in the presence of meningitis or brain abscess. Digital examination of the rectum may be postponed if the patient is acutely ill but in women a sufficiently complete pelvic examination should be performed to rule out the possibility of an infected abortion which often leads to metastatic bacterial pneumonia.

**Laboratory Findings** The most important laboratory findings in pneumococcal pneumonia may be grouped under the following headings:

**1 Findings Indicating the Presence of an Acute Infection** As in most acute infections of bacterial etiology the total leukocyte count in pneumococcal pneumonia is elevated and there is a "shift to the left" in the differential count; the erythrocyte sedimentation rate is also increased. The number of leukocytes in the peripheral blood during the active infection usually ranges from 15,000 to 40,000 per cu mm; counts above 40,000 are occasionally encountered. Leukopenia (with a "shift to the left") is observed in fulminating pneumococcal infections, particularly in the presence of bacteremia.

**2 Findings Indicating Pulmonary Consolidation** Although the presence and location of the pulmonary lesion can usually be determined by physical examination, confirmatory roentgenographic evidence is often helpful. Patients seen in the hospital should either be fluoroscoped (on a stretcher if necessary) or subjected to roentgenographic examination. Both postero-anterior and lateral views of the chest should be taken. The lateral film may be of great value in (a) detecting retrocardiac consolidation in the left lower lobe, (b) indicating whether a lesion visible in the postero-anterior view is located anteriorly or posteriorly and thus in what lobe it is situated, and (c) identifying interlobar accumulations of fluid (Fig. 21 a b). If the patient is too ill to be subjected to such a complete examination, a portable chest film should be taken at the bedside. Proper management of pneumococcal pneumonia in the home does not necessarily require roentgenographic examination.

**3 Findings Indicating Etiology** When ever the diagnosis of pneumococcal pneumonia is suspected, blood should be drawn for culture. Anaerobic (thioglycollate broth) as well as aerobic cultures are recommended since many strains of pneumococci multiply most readily at a reduced oxygen tension. A positive blood culture not only affords clear-cut evidence regarding

etiology but also gives valuable information concerning prognosis. The physician should make a real effort to obtain a suitable specimen of sputum. Whenever possible the patient should be made to expectorate mucus raised directly from the bronchial tree; secretions from the nasopharynx may be unsatisfactory. The specimen should be taken to the laboratory immediately to be cultured (inoculated intraperitoneally in a mouse and smeared for Gram stain). When typing serums are available, direct typing of the sputum should be attempted and if unsuccessful the pneumococci isolated by culture or mouse inoculation should be identified by the quellung technique. The practical importance of pneumococcal typing today is limited but is of some value in differential diagnosis as noted below. In the days of serum therapy however, specific treatment could not be begun until the type of the infecting organism had been determined. When no sputum specimen can be obtained from the patient, a throat swab may be cultured. Although it is not a hazardous procedure, lung puncture is now rarely used to determine the etiology of acute bacterial pneumonia.

Other laboratory examinations which may be of value in the management of the patient include the measurement of serum sodium and chloride. During the acute phase of bacterial pneumonia there may be a profound disturbance in electrolyte metabolism characterized by (a) depressed urinary excretion of sodium chloride and (b) decrease in the concentration of sodium and chloride in the serum. Both these changes appear to be due to transfer of sodium chloride from plasma and extracellular fluid. In particularly severe infections hyponatremia and hypochloremia may be associated with "prerenal" azotemia and shock. The exact mechanism of the electrolyte disturbance is at present not known.

**Clinical Course** During the course of the disease the patient should be examined carefully once a day. More frequent physical examinations may unduly exhaust an acutely ill subject. The common complications of pneumococcal pneumonia should be specifically looked for during each examination, particularly when fever persists.

**Defervescence** The fever of untreated pneumococcal pneumonia may either terminate abruptly by "crisis" five to ten days after the onset or may gradually subside by lysis. When effective antibacterial therapy is used a dramatic crisis often ensues within twenty-four hours. Sometimes a

uncommon in only moderately severe cases. As in any bedridden patient phlebotrombosis may occur during pneumonia. Its presence should suggest the possibility that the pulmonary lesion is due to infarction of the lung rather than to primary pneumonia. *Herpes labialis* occurs in 5 to 40 per cent of patients with pneumococcal pneumonia and constitutes an essentially benign complication. Occasionally the herpetic lesions become secondarily infected causing mild pyoderma.

**Differential Diagnosis.** The symptoms and signs of pneumococcal pneumonia are usually so characteristic as to make the diagnosis relatively simple. Atypical cases occasionally occur in which a definitive diagnosis cannot be made and in which antimicrobial treatment on suspicion is justified. Sometimes the disease is mistaken for less serious forms of respiratory tract infection such as acute tracheobronchitis or "grippe." This error can often be avoided if proper significance is attached to the history of chills, bloody sputum and chest pain if the lungs are carefully examined at frequent intervals for signs of pulmonary consolidation and if postero-anterior and lateral roentgenograms are made of the chest.

Pneumonia due to organisms other than pneumococcus may at times be difficult to differentiate from pneumococcal pneumonia. Only by bacteriological study of the sputum can pneumonia due to Friedlander's bacillus *Staphylococcus aureus* or group A beta hemolytic streptococcus be identified. Tuberculous pneumonia rarely causes the acute prostration characteristic of coccidial infection. Primary atypical pneumonia and other viral and rickettsial infections of the lungs such as psittacosis and Q fever do not often cause shaking chills, diffusely bloody sputum, severe pleural pain or a marked leukocytosis, although they may at times be confused with acute bacterial pneumonia (see p. 135). Tularemic pneumonia must also be considered. When the diagnosis is in doubt repeated examinations of the sputum should be made using both the Gram and Ziehl-Neelsen stains. Sputum specimens should not only be cultured but should be injected into mice. The identification of one of the lower types of pneumococcus (excluding type III) constitutes strong circumstantial evidence in favor of the diagnosis of pneumococcal pneumonia. Specific diagnosis of pneumonia is of great practical importance because of therapy. Whereas tuberculous, tularemic and Friedlander's bacillus pneu-

monia respond to streptomycin and individual instances of primary atypical pneumonia might be influenced by the tetracycline drugs, most other forms of acute pneumonia are best treated with penicillin.

**Nonpulmonary Bacterial Infections.** Bacterial infections other than pneumonia must be considered in the differential diagnosis. Pleurisy involving the outer part of the diaphragm and resulting from right lower lobe pneumonia often causes referred pain to the right side of the abdomen thus simulating acute appendicitis. Subdiaphragmatic abscess arising from perforation of the appendix conversely may simulate pneumonia. Acute pyelonephritis with chills, fever, flank pain and leukocytosis must not be confused with pneumonia; the diagnosis is usually established by examination of the urine and by the absence of signs of frank consolidation in the lungs. Differentiation of acute pyelonephritis from pneumococcal pneumonia is of primary importance since most urinary tract infections are caused by organisms that are not susceptible to penicillin.

**Noninfectious Diseases.** Among the essentially noninfectious processes which must be differentiated from pneumococcal pneumonia are congestive heart failure, pulmonary infarction and atelectasis. That congestive heart failure predisposes to acute bacterial pneumonia has already been emphasized. The two conditions not infrequently coexist but occasionally congestive heart failure is mistaken for pneumococcal pneumonia. This error is most frequently made in cases with dyspnea, cough, blood-streaked sputum and signs in the chest which simulate those of consolidation but in reality are due to pleural effusion. In such cases the absence of high fever and leukocytosis and the presence of distended neck veins and peripheral edema usually suggest the correct diagnosis.

**Pulmonary infarction** on the other hand is more difficult to differentiate from pneumonia. The dyspnea, pleural pain, hemoptysis, fever, physical signs of pulmonary consolidation, roentgenographic findings and leukocytosis are all in keeping with an acute infection of the lungs. Not infrequently however the initial symptom is intense pleural pain of explosive onset, shaking chills rarely occur, there is no preceding history of respiratory infection, the fever usually is not high, frank hemoptysis is common, pulmonary signs when present appear early and the total leukocyte count rarely reaches 20,000 per cu

tions of pneumococcal pneumonia which are often associated with one another are endocarditis and meningitis. Eighteen out of nineteen cases of pneumococcal endocarditis described by Ruegesegger were complicated by the presence of meningitis. Endocardial infection which occurs most commonly on the aortic valve may be suggested by repeated chills, persistent fever and leukocytosis and the presence of a cardiac murmur. The diagnosis is established by the identification of embolic phenomena (see Bacterial Endocarditis) and by the demonstration of persistent bacteremia. Only rarely does recovery occur without treatment. Equally serious is pneumococcal meningitis resulting from blood borne metastasis to the meninges. Its presence is indicated by the usual manifestations of meningitis (headache, nausea and vomiting, stiff neck, positive Kernig's sign, stupor and so forth) and the diagnosis is established by the demonstration of purulent cerebrospinal fluid containing pneumococci. The meningitis is characterized by the presence in the pia arachnoid of a heavily infected exudate which may cause subarachnoid block or lead to localized subarachnoid abscesses. Unless vigorous therapy is instituted promptly the prognosis is hopeless.

**Pericarditis.** Like the other complications of pneumococcal pneumonia, pericarditis has also become relatively rare since the introduction of potent antimicrobial drugs. When the pericardium is invaded the patient usually experiences precordial pain and a leathery friction rub may be heard over the heart. Pericardial effusion usually results, causing a dampening of the heart sounds. If the fluid is sterile the condition is benign unless so large a volume accumulates as to cause cardiac tamponade. Empyema of the pericardium, on the other hand, is a serious complication requiring prompt and vigorous treatment. If it is allowed to persist, untreated purulent pericarditis may gradually heal but will often lead to pericardial calcification. Years later, serious constriction of the heart may result from contraction of the healed lesion.

**Other Specific Complications.** Still rarer specific complications include peritonitis, pyogenic arthritis, metastatic cutaneous abscesses and nephritis. The last of these usually occurs several weeks after the pneumonia, the latent period appearing to be similar to that in nephritis following group A streptococcal infection. Occasionally the pulmonary lesion of pneumococcal pneumonia fails to resolve even after many

weeks and finally becomes replaced by fibrous tissue. This complication is termed organized pneumonia and rarely causes serious disability unless accompanied by suppuration.

**Nonspecific Complications.** Three nonspecific complications of importance occur not infrequently during the acute phase of pneumococcal pneumonia: paralytic ileus, peripheral vascular collapse (shock) and congestive heart failure. Ileus occurs particularly in patients suffering from anoxia and severe toxemia and gives rise to gaseous distention of the abdomen (tympanites) which causes discomfort and often increases respiratory embarrassment. Shock likewise is a complication of severe toxemia and indicates a serious prognosis. The circulatory disturbance is characterized by hemoconcentration, an increased rather than a depressed cardiac output and peripheral vasodilatation. Whether "toxic myocarditis" also plays a role is uncertain. The skin, particularly of the extremities, is cold and moist and exhibits a characteristic gray cyanosis. Peripheral vascular failure when present for a sufficient length of time becomes irreversible and the patient eventually dies in shock despite the fact that the infection in the meantime may have been adequately controlled by chemotherapy. Congestive heart failure which also occurs not infrequently as a complication of severe pneumonia, particularly in patients with underlying heart disease, must be differentiated from peripheral vascular collapse for the proper methods of treating the two conditions are different. Since congestive heart failure is an important predisposing factor in bacterial pneumonia, it is not surprising that they are often associated and obviously both must be treated. The diagnosis of congestive heart failure in the presence of pneumonia may at times be difficult but should be considered in any patient with abnormal distention of neck veins, peripheral edema, an enlarged tender liver, elevated venous pressure and a prolonged circulation time. Pulmonary signs of congestion may be unreliable, particularly if the pneumonia is bilateral.

**Jaundice.** The pathogenesis of which appears to be related to increased hemolysis of the erythrocytes in the pneumonic lesion and depressed liver function resulting from anoxia, occurs most often in patients who have severe pneumonia and have had a poor diet. The presence of prominent icterus usually indicates a poor prognosis, although slight hyperbilirubinemia is not

to seven days. Not infrequently a secondary rise in temperature occurs after the crisis. This elevation is usually low grade and subsides spontaneously within a few hours or at most a few days. Such secondary fever must be distinguished from that caused by complications or continued pulmonary infection and can usually be recognized by the fact that it is accompanied neither by symptoms of continued toxicity nor by significant leukocytosis.

When a patient fails to respond within forty-eight hours to penicillin therapy, three possible explanations should be considered: (a) that the patient is suffering from a serious complication such as empyema, endocarditis or meningitis; (b) that the primary infection is of nonpneumococcal etiology and is due to an agent that is resistant to the antimicrobial action of penicillin; or (c) that drug fever has developed as a result of penicillin hypersensitivity. Lack of response to penicillin cannot be explained on the basis of a penicillin-resistant strain of pneumococcus, since such strains are rarely if ever encountered in human pneumonia. Occasionally patients will respond initially to treatment only to have unmistakable signs of persistent pneumonia subsequently develop in spite of continued therapy. This sequence of events is usually due to the presence of a mixed infection; the initial response to treatment resulting from control of penicillin-susceptible organisms and the relapse occurring as a result of secondary invasion by penicillin-resistant species. Immediate institution of combined therapy with streptomycin, erythromycin or a tetracycline drug is indicated in all such cases.

Toxic reactions to penicillin are rarely of sufficient severity to warrant discontinuation of treatment. Urticaria may be bothersome and a combination of symptoms and signs suggesting "serum sickness" occasionally occurs. Patients with dermatophytosis may experience an exacerbation of the lesions during penicillin therapy.

**SULFONAMIDES.** Sulfonamides such as sulfathiazole, sulfadiazine and sulfamerazine, although effective in the treatment of pneumococcal pneumonia, should not be used for the following reasons: (1) Penicillin is a more potent antibacterial agent than the sulfonamides; it causes more prompt destruction of the bacteria and it is far more effective in controlling purulent complications; and (2) toxic reactions to sulfonamides (particularly to sulfathiazole) are significantly more common than to penicillin and include such

conditions as toxic nephritis and periaortitis nodosa, which may terminate fatally. There is no conclusive evidence that combined penicillin-sulfonamide therapy is any more effective than treatment with penicillin alone, except possibly in the presence of meningitis or in the case of mixed infections involving penicillin-resistant organisms. In the latter situation other antimicrobial drugs (see above) rather than sulfonamides should be combined with penicillin.

**ANTISERUM.** Type-specific antiserum is no longer used in the treatment of pneumococcal pneumonia.

**THE TETRACYCLINE DRUGS AND CHLORAMPHENICOL.** may be used in the treatment of acute bacterial pneumonia. When the diagnosis of pneumococcal pneumonia is not clearly established, it may be advisable to use one of the tetracyclines (0.5 to 1.0 gm. by mouth every six hours) because of their broader antibacterial action and their possibly beneficial effect in primary atypical pneumonia. Staphylococcal enteritis may result from the use of "broad spectrum" antibiotics such as the tetracyclines and if not promptly treated may be fatal. Erythromycin is less effective than penicillin or the tetracyclines in pneumococcal pneumonia and should be used (0.3-0.5 gm. every six hours) only when the lesion is suspected of harboring penicillin-resistant staphylococci.

**Supportive Treatment.** Patients suffering from pneumococcal pneumonia should be kept at bed rest and visitors to the sick room should be limited to the immediate family. Pleural pain if mild may be treated with codeine sulfate (30 to 60 mg.) orally and if severe with subcutaneous morphine sulfate (10 to 15 mg.) or an equivalent analgesic such as methadone hydrochloride (5 to 10 mg. subcutaneously). A tight chest binder is sometimes helpful in providing something to cough against. Restlessness and insomnia, which are most commonly associated with delirium, are best controlled by paraldehyde (4 to 12 ml. by mouth or 10 to 20 ml. in 20 to 30 ml. of olive oil by rectum). Dyspnea and cyanosis should be treated with oxygen administered by tent (40 to 60 per cent oxygen) or by nasal catheter (35 to 50 per cent oxygen when gas is delivered at 4 to 7 liters per minute). Oxygen masks are usually unsuitable because of the patient's cough and expectoration.

**FLUID AND ELECTROLYTES.** During the acute stage of pneumococcal pneumonia, considerable fluid is lost from the body

mm When a pulmonary infarct becomes infected as not infrequently happens differentiation from primary bacterial pneumonia may be extremely difficult. Although in such cases the patients should receive antimicrobial treatment as in pneumonia recognition of the infarction is of importance because of the need for anticoagulant therapy.

*Pulmonary atelectasis* resulting from bronchial obstruction not only may simulate pneumonia but often leads to serious infection of the lung if the bronchial obstruction is not relieved. Aspiration of mucus during or after surgical anesthesia is a common cause of atelectasis. Dyspnea, cough, chest pain, splinting of one side of the thorax, dullness to percussion and suppressed breath sounds may all suggest primary pneumonia. Fever and leukocytosis also are noted when infection is present. Since pulmonary atelectasis may be relieved by forced coughing and postural drainage or if necessary by bronchoscopy it is important to differentiate it from primary pneumonia. Occasionally sufficient shift of the mediastinum occurs to make the diagnosis obvious. Collapse of a segment of the lung may also result from chronic bronchial obstruction due to bronchogenic carcinoma or aortic aneurysm.

Even when the diagnosis of pneumococcal pneumonia is established beyond doubt the possibility of a second underlying lesion of the lung must be borne in mind. Bronchiectasis may lead to repeated attacks of bacterial pneumonia and often becomes evident only after the pneumonic consolidation has resolved. Bronchogenic carcinoma as well as pulmonary tuberculosis must likewise be looked for during the follow up examination.

**Treatment** The treatment of pneumococcal pneumonia may best be discussed under three headings: (a) antimicrobial therapy, (b) supportive measures and (c) the treatment of complications. Before the advent of effective antibacterial therapy supportive treatment was of the greatest importance. The introduction first of antipneumococcal serum and later of sulfonamides, penicillin and the other antimicrobial drugs has so altered the management of pneumococcal pneumonia that today supportive treatment is rarely crucial and serious complications are only occasionally encountered.

**Antibacterial Therapy** **PENICILLIN** Penicillin is at present the drug of choice in the treatment of pneumococcal pneumonia. Most strains of the organism are extremely

susceptible to penicillin and are inhibited in broth culture by concentrations of less than 0.01 unit per ml. The effectiveness of antimicrobial treatment is due in part to the natural resistance of the host which accounts for the destruction of a large proportion of the invading bacteria. Host resistance which results primarily from the activity of phagocytic cells in the lung when combined with the bacteriostatic and bactericidal effects of drug therapy controls promptly all but the most malignant pneumonia. Even with no treatment at all approximately seven of every ten patients with pneumococcal pneumonia eventually recover.

Conventional penicillin therapy involves the intramuscular administration of 300,000 or 400,000 units two to four times each twenty-four hour period depending upon the severity of the infection. Treatment should be maintained for at least one week if treatment is discontinued too soon relapse of the infection occurs. Since penicillin continues to exert a bacteriostatic effect for several hours after the drug has been removed from the site of infection the interval between injections may be as long as twelve hours provided large enough doses (300,000 to 600,000 units) are given. In severe infections however it is safest to give the drug at least every six hours.

Penicillin may also be given by mouth. When oral penicillin is used it must be prescribed in doses five times as large as those used intramuscularly since only 20 to 30 per cent is absorbed from the gastrointestinal tract and it should not be given just preceding or immediately following a meal. Slowly absorbed (depot) penicillin in the form of the procaine salt may be injected intramuscularly in doses of 300,000 units once or twice a day. This form of treatment though convenient to both patient and physician should not be relied upon in severe infections since the blood levels attained are considerably lower than those resulting from multiple injections of aqueous penicillin. In the presence of shock aqueous penicillin should be given intravenously.

Response to penicillin therapy is usually dramatic. Bacteremia when present at the start of treatment clears within a few hours. A crisis characterized by rapid defervescence and a striking subsidence of symptoms occurs in less than forty-eight hours in approximately 85 per cent of patients. The remaining 15 per cent experience a more gradual recovery the temperature falling by lysis over a period of three

longstanding purulent exudates which otherwise would be too thick to aspirate through even the largest thoracentesis needle. Loculation also is broken up by the enzymatic débridement. Because of their large molecular dimensions the streptococcal enzymes do not penetrate living cells and therefore are not injurious to tissue or to viable phagocytes. The streptokinase and streptodornase are injected directly into the pleural (or pericardial) space in doses of 200 000 to 400 000 units and 50 000 to 100 000 units respectively. A mild and transient febrile reaction often occurs within a few hours. Several injections may be necessary particularly when the empyema has become loculated. By the use of the streptococcal enzymes combined with daily aspiration and the local injection of penicillin prompt and permanent cures of both acute and relatively chronic empyemas have been effected (Fig 21 c d).

The treatment of the remaining two major complications of pneumococcal pneumonia namely meningitis and endocarditis are discussed elsewhere (see Meningitis and Bacterial Endocarditis).

**Prognosis** The case fatality rate in untreated pneumococcal pneumonia ranges from 20 to 40 per cent. The widespread use of sulfonamide drugs in the late 1930's resulted in a lowering of the fatality rate among treated patients to approximately 10 per cent. Penicillin therapy has lowered the rate still further. At present approximately 95 per cent of patients with pneumococcal pneumonia recover when properly treated with penicillin.

The prognosis in pneumococcal pneumonia is influenced adversely by each of the following: (1) old age (and also in infancy); (2) late treatment; (3) infection with certain types of pneumococci (particularly types II and III); (4) involvement of more than one lobe of the lung; (5) leukopenia; (6) bacteremia; (7) jaundice; (8) the presence of complications (notably shock and meningitis); (9) pregnancy (particularly in the third trimester); (10) the presence of other disease (i.e. heart disease, cirrhosis of liver and so forth); (11) alcoholism. Through a consideration of these factors a rough estimate may be made of the severity of the infection in each individual case and therapy may be modified accordingly.

**Prevention** Since pneumococcal pneumonia is not highly contagious and since it responds promptly to early therapy prophylaxis constitutes less of a problem

than it does in many other infectious diseases. It is estimated that only one in every 500 persons of all ages in the United States may be expected to contract the disease in any one year. In certain closed communities however and in areas where the pneumococcal carrier rate is particularly high epidemics occasionally occur. Under such conditions immunization with pneumococcal polysaccharide may be indicated. During World War II the effectiveness of polyvalent pneumococcal vaccine in preventing pneumonia and in lowering the pneumococcal carrier rate was clearly demonstrated in a controlled experiment on Army personnel. Although immunization may prove to be of value in military medicine its application to the general population is not indicated because the incidence of the disease in ordinary circumstances is too low to justify vaccination. Likewise the use of methods of "air sterilization" by ultraviolet radiation and by aerosols is of limited applicability.

Although pneumococcal pneumonia can undoubtedly be prevented (or at least aborted) in many patients by the intensive treatment of every upper respiratory tract infection with antimicrobial drugs their indiscriminate use for this purpose should be avoided. The possible inconvenience to the patient of hypersensitivity reactions and the theoretical danger of producing drug resistant strains of bacteria outweigh the advantages to be gained in preventing such a relatively uncommon and readily treatable disease as pneumococcal pneumonia. Such chemoprophylaxis during outbreaks of epidemic influenza on the other hand might conceivably be indicated.

**Isolation Procedures** Ideally every patient with pneumococcal pneumonia should be placed in respiratory isolation, all attendants and visitors being required to wear masks when in the patient's room. The isolation precautions should be enforced until the patient has been afebrile for several days. The cross infection rate in pneumococcal pneumonia is low and patients receiving chemotherapy are probably not highly infectious. Hence isolation rules are often disregarded without apparent ill effect. The danger of cross infection in a general hospital particularly among patients with congestive heart failure, pulmonary edema or other severe debilitating diseases may be greater than in the general population.

chiefly through the skin as the result of high fever. Dehydration may develop rapidly and if severe may become a contributing factor in the development of shock. Most patients require between 3 and 4 liters of fluid a day when the fever is high. Because of the loss of salt through the skin and the tendency for the serum sodium to be low during the acute phase of the infection it is advisable to supplement the intake of sodium chloride with 1 per cent salty broth. A total daily intake of 6 to 10 gm of salt is usually sufficient. Intravenous saline may be used if the patient is unable to take fluid by mouth. In the presence of congestive heart failure the use of supplementary sodium chloride is contraindicated. In the absence of renal disease glycosuria or congestive heart failure the patient's state of hydration may be estimated by the specific gravity of the urine. When hydration is adequate the specific gravity should remain below 1.020.

**DIET** Many patients with pneumococcal pneumonia are too ill to tolerate a full diet and should receive only liquids during the height of the fever. Fruit juices, ginger ale and soups are well tolerated. After the crisis a regular diet may be prescribed.

The patient should be kept in bed until the temperature has been normal for several days and should be observed closely until the pneumonic lesion has resolved. As already emphasized all patients should be subjected to a follow-up roentgenographic examination three to four weeks after recovery.

**Treatment of Complications** **SHOCK** Patients with peripheral vascular collapse (shock) resulting from severe pneumococcal pneumonia usually respond poorly to the accepted forms of antishock therapy. The prognosis is almost invariably grave when this complication develops. Oxygen therapy should be begun immediately even if cyanosis is absent. Norepinephrine is at present the best drug available for combating peripheral vascular collapse. It should be given continuously by intravenous drip in sufficient amounts to maintain the systolic pressure at levels between 100 and 110. Enough norepinephrine (one vial contains 4 mg) must be added to each liter of salt solution so that the hypotension can be controlled by the administration of not more than 2000 to 3000 ml of fluid in twenty-four hours. Hydrocortisone given intravenously may also be of value (300 mg during the first twenty-four hours with daily dose decreased thereafter to 50 or 100 mg). These measures should be used

only with the greatest caution if signs of congestive heart failure are also present. The treatment of congestive heart failure in patients with pneumococcal pneumonia is essentially the same as the treatment of heart failure under other conditions (see *The Treatment of Congestive Heart Failure*).

**ABDOMINAL DISTENTION** Abdominal distention (paralytic ileus) is best managed by the use of daily enemas, the insertion of a rectal tube, the administration of oxygen, the application of heat to the abdomen (warm turpentine stupes) and repeated hypodermic injections of prostigmine methylsulfate (0.5 mg). The prostigmine injections should be repeated every hour until a definite effect is obtained; subsequent doses should be spaced at intervals of two to four hours and maintained as long as is necessary.

Delirium may sometimes be difficult to control, particularly in patients with a history of chronic alcoholism. The use of 30 to 90 ml of whisky per day may quiet alcoholic patients during the acute phase of the disease. The safest hypnotic to use is paraldehyde. A restraining net over the bed is often required to prevent the patient from climbing out of bed and injuring himself.

**EMPHYEMA AND PERICARDITIS** The treatment of empyema and of purulent pericarditis until recently has always been surgical. During World War I Graham demonstrated that open thoracotomy must always be delayed until the pus aspirated from the chest is relatively thick and the area of infection is sufficiently well walled off to prevent marked shift of the mediastinum. Since the advent of penicillin cases of both empyema and pericarditis have been successfully treated by repeated aspiration and injection of aqueous penicillin (50,000 to 200,000 units daily) through a thoracentesis needle. More recently Tillett and his co-workers have demonstrated that the treatment of empyema without surgical drainage is greatly facilitated by the use of two enzyme preparations obtained from filtrates of beta-hemolytic streptococci. The first of these enzymes, streptokinase, activates the fibrinolytic system in plasma and thereby causes lysis of the fibrin contained in purulent exudates. The second enzyme, known as streptodornase (abbreviation for streptococcal deoxyribonuclease), brings about depolymerization of the deoxyribonucleoprotein. By lysing both the fibrin and the nucleoprotein, the streptococcal enzymes cause a dramatic liquefaction of

symptoms of catarrhal inflammation of the upper respiratory tract and a more or less severe febrile reaction accompanied by malaise headache and muscular aching.

The mortality rate in epidemic influenza is low and secondary bacterial pneumonia is relatively uncommon. During recent years cases of associated staphylococcal pneumonia have occurred in some outbreaks and this was especially true in the epidemic caused by the Asian variety of type A influenza virus which occurred during the fall and winter of 1957-1958. The incidence of pulmonary involvement attributable to the virus itself has varied considerably in different epidemics but in the majority it has been small. However it should be remembered that the virus alone in the proper circumstances can cause a fulminating and fatal pneumonia.

For further information on influenzal pneumonia see the section on Influenza (p 10).

#### Q FEVER PNEUMONIA

Q fever has been found to have virtually a world wide distribution and serological surveys have revealed evidence of its presence in nearly all parts of the United States. The etiological agent is a filter passing species of rickettsia *Coxiella burnetii*. Although the infection is essentially systemic it is usually but not always accompanied by a more or less extensive pneumonitis. Cases with pulmonary involvement present a clinical picture and roentgenographic findings indistinguishable from those of primary atypical pneumonia. The disease responds readily to treatment with a tetracycline drug.

For further information on Q fever see the section on Rickettsial Diseases (p 109).

#### PNEUMONIA IN SMALLPOX

Pulmonary lesions occur frequently in smallpox. Variola virus produces a specific bronchopneumonia with characteristic inclusion bodies in many of the affected cells. The pneumonia may be a serious complication since there is a pronounced predisposition to secondary invasion by pyogenic bacteria particularly staphylococci.

#### PNEUMONIA IN CHICKENPOX

A diffuse and sometimes fatal bronchopneumonia occurs occasionally in chickenpox especially among adult patients (see Varicella p 28). In a number of autopsied cases the absence of bacteria and the character of the pathological findings have

indicated that the pulmonary lesions may be caused solely by the virus. The administration of cortisone in severe cases has proved to be beneficial and even life saving in some instances.

#### PNEUMONIA IN MEASLES

Bronchopneumonia occurs frequently in measles. The pneumonitis resembles other forms of viral pneumonia and is often caused solely by a specific reaction to the measles virus. Superimposed bacterial infection is common however and accounts for the majority of the severe or fatal cases. *Streptococcus haemolyticus*, *Staphylococcus aureus* and *Hemophilus influenzae* are the usual secondary invaders. In recent years the mortality rate from measles pneumonia has been markedly reduced by treatment with antimicrobial drugs. Penicillin is the agent of choice in most instances.

#### PNEUMONIA IN LYMPHOCYTIC CHORIOMENINGITIS

Lymphocytic choriomeningitis is caused by a specific viral agent. The disease in man is usually characterized as an acute aseptic meningitis but occasionally a grippelike syndrome is produced without clinical evidence of central nervous system involvement. Several cases with pulmonary involvement have also been described and the virus has been isolated from the lung at necropsy.

#### PNEUMONIA IN ADENOVIRAL INFECTIONS

Pneumonia has been frequently observed in association with infection by adenoviruses particularly types 4 and 7 among military recruits. The clinical characteristics of the disease are similar to those of primary atypical pneumonia but significant increases in titer of cold hemagglutinins or of agglutinins for streptococcus MG do not occur.

For further information see the section on Common Upper Respiratory Disease.

#### PNEUMONIA CAUSED BY UNIDENTIFIED VIRAL AGENTS OR AGENTS PRESUMED TO BE VIRUSES

##### PNEUMONIA IN INFECTIOUS MONONUCLEOSIS

Infectious mononucleosis is generally considered to be a viral disease although the etiological agent has not been isolated and identified. A more or less extensive bronchopneumonia may sometimes accompany the infection though it is rarely a dominant feature. Respiratory symptoms

## Other Forms of Acute Bacterial Pneumonia

The pneumonias produced by staphylococci, streptococci or *Klebsiella* (Friedland or *Erbs* bacillus) are described in the sections devoted to infections with these bacteria.

## Pneumonia Due to Viral Agents

A primary type of bronchopneumonia may be caused by numerous known viruses as well as by at least one species of rickettsia and may also result from infections which are presumably viral in nature even though the specific agents have not yet been definitively isolated and identified. These diverse etiological forms of nonbacterial pneumonia have become increasingly prominent and important within recent years largely as a consequence of progressive improvements in antibacterial chemotherapy together with wider diagnostic use of serological procedures and the newer methods of tissue culture. The clinical features in most cases can be readily distinguished from those that characterize primary bacterial pneumonia and they apparently depend not so much upon which viral agent is responsible as they do upon the nature and the extent of pulmonary involvement including in some instances the occurrence of superimposed bacterial infection. Thus the physician is confronted with a situation in which different viral agents may cause identical patterns of pulmonary disease or the same agent may give rise to a pneumonitis that varies considerably in its clinical aspects. The difficulty of the

problem is further increased by the fact that precise etiological diagnosis depends upon isolation of the causative agent or demonstration of a specific antibody response. Both of these procedures require somewhat specialized laboratory techniques as well as an element of time particularly for serological tests which often makes their results useful only in retrospective analysis of the patient's illness. Moreover it is obviously impossible exactly to determine etiology in those cases for which ■ yet unidentified viral agents are responsible.

As Reimann has indicated the nomenclature of this group of pulmonary infections is of more than semantic interest. Through habit, convenience and the all too frequent lack of adequate diagnostic information the loose expression "atypical pneumonia" has become popular as a general descriptive term. But it must be emphasized that these etiological and clinical entities are typical in their own right and are atypical only when compared with classic pneumococcal pneumonia. The writer agrees with Reimann that viral pneumonia is a more appropriate designation and that it is "broad enough to cover all viral pulmonary infections and tentatively those of probable viral origin in anticipation of the discovery of their causes. An exception may currently be made for primary atypical pneumonia is discussed under Psittacosis, ment of cold hemagglutinins.

## PNEUMONIA CAUSED BY KNOWN VIRUSES AND RICKETTSIAE

### PSITTACOSIS

(Ornithosis)

Pneumonia may be caused by several closely related viruses of the psittacosis lymphogranuloma group. This form of pneumonia ■ discussed under Psittacosis (p. 43).

### VIRUS INFLUENZAL PNEUMONIA

Since the identification of the virus of influenza by Smith, Andrewes and Laidlaw in 1933 widespread epidemics localized outbreaks and sporadic cases of this disease have been repeatedly recognized in nearly all parts of the world. Influenza is now known to be caused by a group of viruses most of which can be classified as either influenza A or influenza B according to their antigenic characteristics. At least two other antigenic types of virus are known to exist. The infection typically causes a grippelike syndrome with sudden onset.

normal persons and of those suffering from acute infections of the respiratory tract without pulmonary involvement. Moreover in the transmission experiments previously mentioned the microorganism was isolated from human volunteers with equal frequency both before and after successful inoculation. It should also be noted that streptococcus MG is quite susceptible to penicillin whereas penicillin has no effect on the course of primary atypical pneumonia.

**Epidemiology.** The disease tends to occur in sporadic form but numerous localized outbreaks have been reported especially in semiclosed and crowded population groups such as schools and military establishments. Among personnel of the armed forces it was more common than all other forms of pneumonia during World War II. Epidemiological studies and transmission experiments indicate that the disease is spread directly from person to person via the respiratory route by infected discharges from the nose and mouth. The communicability is often low and there is usually no history of contact. In early epidemiological surveys the frequent failure to establish a history of contact was puzzling until it became apparent that there are many mild or unrecognized cases of the disease. Patients hospitalized on open wards rarely transmit their infection to other patients but the relatively high incidence among physicians, nurses and other hospital personnel serves to emphasize the importance of contact as well as the frequency of exposure in transmission. Occasionally the disease seems to have an enhanced communicability in which case the history of antecedent contact may be readily obtained and the patients appear to transmit their disease more easily to other persons. The factors responsible for this phenomenon have not been determined.

All age groups are affected but the disease is recognized most frequently among persons in early or middle adult life. There is no predilection for sex, race or color. The disease is widespread in the northern temperate zone and is relatively rare in the tropics. Cases occur throughout the year although the greatest incidence is during the winter months. In some years the disease has been prevalent during middle and late summer but in general it tends to parallel the combined incidence of upper respiratory tract infections. The factors which influence susceptibility and resistance have not been established.

The period of communicability is un-

known. One attack appears to confer at least temporary resistance to reinfection but the duration and quality of such immunity have not been determined. The occasional occurrence of second attacks after an interval of apparent health indicates that immunity does not persist indefinitely in all patients.

**Morbid Anatomy.** Since the mortality rate is low there has been relatively little opportunity to study pathological changes in the lungs or elsewhere in the body. The available postmortem studies indicate that the pulmonary lesions are not distinctive and probably cannot be differentiated from those of psittacosis, Q fever and other non-bacterial pneumonias. Characteristically there is a more or less extensive patchy bronchopneumonia with areas of hemorrhagic consolidation in various stages of evolution. The bronchi appear inflamed and contain mucoid or mucopurulent exudate. Localized atelectasis or emphysema may be present as the result of bronchial obstruction. The pleura may show patches of fibrinous exudate and occasionally the pleural cavity contains small amounts of fluid. Large pleural effusions are uncommon. Enlargement of the tracheobronchial lymph nodes has been observed in some cases.

**Microscopic examination** generally reveals an interstitial type of pneumonia most prominent in regions adjacent to bronchi and bronchioles. The alveolar septums appear thickened with dilatation of the capillaries, infiltration by lymphocytes and monocytes and varying degrees of edema. Polymorphonuclear leukocytes are relatively few. The alveolar spaces contain some edema fluid or a scanty exudate in which either mononuclear cells or erythrocytes may predominate. Bacteria appear to be absent or are few in number. Occasionally the alveoli and smaller bronchioles may be lined by hyaline membranes. Peribronchial and perivascular infiltration by mononuclear cells is sometimes marked in extent. The epithelium of the bronchi is usually intact although areas of necrosis and sloughing may be seen particularly in the smaller bronchi and bronchioles. In these areas of necrosis polymorphonuclear cells are numerous. Large numbers of polymorphonuclear cells are also seen in the exudate within bronchial lumina. Intracellular inclusion bodies and elementary bodies have not been demonstrated.

In some cases clinical evidence of encephalitis has been accompanied by demonstrable lesions of the brain. Microscopic

are usually mild or absent and the pulmonary involvement may be discovered only incidentally on roentgenographic examination

#### PNEUMONIA IN FRYTHEMA EXUDATIVUM MULTIFORME

A nonbacterial pneumonia occurs frequently in the more severe forms of erythema exudativum multiforme (Stevens Johnson syndrome) although it rarely occurs in milder forms of the disease as originally described by Hebra. The pneumonia is considered to be an integral part of the disease and in its clinical features closely resembles primary atypical pneumonia. The etiology has not been determined but it is generally believed that the causative agent is a virus. In some cases there is evidence that infection with the virus of herpes simplex may have been responsible.

#### PRIMARY ATYPICAL PNEUMONIA

**Definition** Primary atypical pneumonia is an acute infectious disease of the human respiratory tract in which pulmonary infiltration of varying degree is a prominent feature. The causative agent is in all probability a virus although it has not been definitely isolated and identified. Certain other viral and rickettsial diseases of known etiology may clinically resemble primary atypical pneumonia including psittacosis or ornithosis, influenza, lymphocytic choriomeningitis and Q fever.

**History** There is some indication that primary atypical pneumonia is not a disease of recent origin but possibly has existed for a century or more. However, in the older literature it is impossible to distinguish this form of pneumonia from influenza and many other infections of the respiratory tract. Contemporary knowledge began to accumulate between 1930 and 1940 when a series of reports were published which described localized outbreaks of the disease, emphasized its apparently rising incidence, defined its clinical characteristics and presented evidence that none of the usual bacteria were etiologic factors. An important factor in the recognition of primary atypical pneumonia was the introduction between 1938 and 1940 of sulfonamide derivatives for the successful chemotherapy of pneumococcal and streptococcal pneumonia. The failure of primary atypical pneumonia to respond to treatment with these drugs and later to the even more effective drug penicillin clearly established its distinction from the common bacterial pneumonias and contributed greatly to its present classification as a clinical and etiologic entity.

**Etiology** There seems little reason to doubt that primary atypical pneumonia is caused either by a single virus or by a group of closely related viruses. During World War II carefully controlled experi-

ments by the Commission on Acute Respiratory Diseases showed that the disease could be transmitted from man to man by spraying the nose and throat of healthy human volunteers with pooled sputum and throat washings collected from active cases. Transmission was effected not only with these untreated inocula but also with the same materials freed of bacteria by passage through sintered glass or Seitz filters. The characteristic illness which resulted in a considerable proportion of the subjects was again successfully passed from them to fresh volunteers by the same method. Of great interest was the fact that minor respiratory illnesses differing from primary atypical pneumonia also developed in other subjects of the same experimental group. This raised the question whether the same filterable agent could be responsible for several clinical varieties of infection or whether the inocula actually contained more than one type of virus. The results of later studies by the Commission indicated that the latter possibility was probably correct although it is still uncertain whether all cases of primary atypical pneumonia are caused by a single infectious agent.

Many attempts have been made in the laboratory to transfer the infection from man to a wide variety of mammalian and avian species. None have been unequivocally successful. Eaton and his associates claimed the isolation of a virus which produces pulmonary lesions in cotton rats and hamsters can be propagated in the developing chick embryo and is specifically neutralized by the convalescent sera of patients.

No bacteria have been identified as etiologic factors although pneumococci, hemolytic streptococci, staphylococci and more rarely other pathogens may be recovered in cultures of the throat or sputum early in the disease. Thomas and his co-workers isolated a serologically distinct nonhemolytic streptococcus (streptococcus MG) from the lungs of fatal cases of primary atypical pneumonia and demonstrated specific antibodies to this microorganism in the blood of about 50 per cent of patients during their convalescence. These observations led to the hypothesis that streptococcus MG might play an etiologic role by functioning as a symbiont together with a virus in a manner analogous to the role of *Hemophilus influenzae* in swine influenza. Later studies have shown however that streptococcus MG occurs not infrequently in the upper respiratory tract of

tients During or after the illness the serums of the majority of patients contain increased titers of cold hemagglutinins or of agglutinins for streptococcus MG

**Clinical Course** The clinical course of primary atypical pneumonia is variable ranging from a mild febrile illness of a few days duration to a severe disease with high temperature which may continue for several weeks In the average case of moderate severity the temperature is elevated for about ten days and falls to normal by lysis Symptoms usually abate as the fever declines although physical and roentgenographic signs of pulmonary involvement usually do not resolve completely until the temperature has been normal for several days A distressing paroxysmal cough is a characteristic feature of the disease and sometimes persists until the pulmonary lesion has cleared entirely The patient's convalescence may be prolonged by sensations of weariness and ease of fatigue

**Complications** are relatively uncommon Secondary bacterial infection occurs so infrequently that the disease seems almost to predispose against it Large pleural effusions are rare Otitis media sinusitis stomatitis tonsillitis bronchiectasis empyema pericarditis and myocarditis have been described Peripheral circulatory collapse has been noted Meningo-encephalitis has been observed clinically and at necropsy In a few cases especially those with high titers of cold agglutinins an acute hemolytic anemia has developed The anemia has appeared usually in patients treated with the sulfonamide drugs but has also been seen in patients who received symptomatic therapy alone its mechanism is not well understood but may be associated in some way with a high titer of cold agglutinins

**Prognosis** The prognosis in primary atypical pneumonia is excellent Although a few instances of death have been reported the uncomplicated disease is self limited in the vast majority of patients including those who may appear severely or even critically ill

**Diagnosis** No specific diagnostic procedures are available but in most cases the diagnosis can be established with reasonable certainty by adequate clinical roentgenographic and laboratory studies The disease may be strongly suspected from the following features gradual onset fever relative bradycardia normal respiratory rate paroxysmal cough and roentgenographic evidence of pneumonia with absent or few physical signs Failure to respond to treatment with penicillin adds support

to the diagnosis but is not a completely reliable criterion Corroborative laboratory findings are a normal or only slightly elevated leukocyte count and normal bacterial flora on culture of the throat or sputum Tests for cold hemagglutinins are helpful in making a definite diagnosis since these peculiar antibodies appear exceptionally in diseases other than primary atypical pneumonia Cold hemagglutination may be demonstrated in approximately 55 per cent of patients although the incidence and magnitude of the titer varies according to the severity and duration of the illness For example the reaction becomes positive in over 90 per cent of patients in whom the disease is severe or prolonged but is positive in only about 20 per cent of mild cases The hemagglutinins do not appear in the serum until the second or third week after onset and the test is therefore of value only in making a late or retrospective diagnosis It is advisable to examine the patient's serum repeatedly for cold hemagglutinins at intervals of five to seven days since a significant rise in titer is more important than a single positive test Tests for agglutinins of streptococcus MG may also be made although these antibodies develop somewhat less frequently than do cold hemagglutinins If either or both of the tests become positive the patient almost certainly has suffered from primary atypical pneumonia but if both are negative it may be difficult or impossible to reach a definite diagnosis

**Psittacosis Q fever influenza and adenoviral infections** with pulmonary involvement may closely resemble primary atypical pneumonia Pneumococcal pneumonia and other acute bacterial infections of the lung not infrequently present similar clinical manifestations especially during the onset and early stages of their development In some cases pulmonary tuberculosis and mycotic infections of the lung must also be considered These diseases can nearly always be identified however either by isolation of the responsible agent or by the eventual demonstration of specific antibodies in the patient's blood Bronchogenic carcinoma pulmonary infarction and bronchiectasis occasionally must be included in the differential diagnosis

**Treatment** Several studies have indicated that the tetracycline drugs may exert a favorable therapeutic effect on the disease but there is some controversy in the literature concerning the validity of these observations In the writer's opinion if the diagnosis seems reasonably certain the

examination has shown focal hemorrhages perivascular cuffing with mononuclear cells and proliferation of astrocytes and glial cells. There is some question whether these changes are directly caused by the viral agent or whether they represent a non-specific tissue reaction which has been seen occasionally in other infectious diseases.

No pathological alterations of note have been described in other organs or tissues.

**Symptoms.** The incubation period usually varies from two to three weeks. In most cases the onset is gradual although occasionally it may be abrupt. During the early stages of the illness the symptoms are not distinctive and generally consist of fever, cough, headache, malaise and chilly sensations. Headache is often distressing or severe. Shaking chills and sweats sometimes occur. Sore throat is not uncommon. Cough is an outstanding feature and its absence makes the diagnosis questionable. The cough at first is dry and paroxysmal but later it usually becomes productive of mucoid or mucopurulent sputum. The sputum is not infrequently blood streaked and in rare instances may be frankly bloody or rusty in appearance. Pain in the chest usually substernal in location and aggravated by cough occurs in many cases. However, typical pleuritic pain is relatively uncommon. Anorexia is often complained of and some patients have nausea and vomiting.

**Physical Findings.** Most patients appear to be acutely but not seriously ill, although exceptions to this rule occur. The temperature may range from 99° to over 105° F, but is usually between 102° and 104° F at the height of the disease. The fever curve may be either sustained or remittent in type.

A relative bradycardia is observed in more than 50 per cent of patients and is of some diagnostic value. The respirations are usually either normal or only moderately increased but in severe cases there may be dyspnea and cyanosis. The nasal and pharyngeal mucous membranes often appear inflamed. Examination of the chest almost always reveals fewer abnormal signs than would be expected from the roentgenographic findings. Some dullness on percussion may be found over the affected pulmonary area. Harshness or diminution of the breath sounds may be detected. Fine or medium rales are usually present and may be the only abnormal signs as the illness progresses they frequently become coarse and moist. Rhonchi are sometimes heard and occasionally may be sharply

localized and intensified on forced expiration indicating bronchial obstruction. Pleural rub and signs of pleural effusion are uncommon. The spleen becomes palpable in rare instances.

**Roentgenographic Findings.** The pulmonary lesions as seen on roentgenograms vary widely in character and distribution. The abnormal shadows may appear mottled, feathery or uniformly opaque with differing degrees of density. In the majority of cases the lesions are most dense in the hilar region and become less dense toward the periphery of the lung field. The margins of the pneumonic areas are usually poorly defined. The lower lobes are most frequently involved although any part of the lungs may be affected. In about 50 per cent of patients the disease is confined to one lobe but in the remainder more than one lobe is affected. Occasionally the pneumonia is migratory and spreads from lobe to lobe with clearing in one area as extension occurs in another. There is nothing characteristic about the roentgenographic changes and a similar picture may be produced by many other infections of the lung including pulmonary tuberculosis.

**Laboratory Findings.** In the majority of cases the total leukocyte count is within normal limits although a slight leukopenia or a moderate leukocytosis may be found. The differential count may show a moderate increase in polymorphonuclear leukocytes but rarely to the degree seen in bacterial pneumonias. Occasionally a brisk leukocytosis is seen during convalescence in the absence of a detectable secondary bacterial infection. The erythrocyte count and hemoglobin values are seldom reduced except in severe prolonged cases or in rare instances of acute hemolytic anemia. The urine may contain a little protein and a few cellular elements as in other infectious diseases. The erythrocyte sedimentation rate usually is moderately elevated at the height of the disease but falls slowly to normal during convalescence. Bacteriological examination of the sputum ordinarily reveals only those microorganisms found normally in the upper respiratory tract. Pneumococci of the higher types may be present. In many cases the bacterial content of the sputum is remarkably scanty. Unlike pneumococcal pneumonia the serum chloride levels as well as the chloride excretion remain within the normal range. Transitory weakly positive Wassermann and other serological tests for syphilis may be obtained with the acute or convalescent phase serums of some pa-

the only product of group A streptococci which is of recognizable significance in the pathogenesis of any of the clinical manifestations of streptococcal disease. This substance is responsible for the erythema in scarlet fever. Persons susceptible to its action may be detected by the injection into the skin of a small amount of a suitable dilution of culture filtrate of a group A streptococcus. A small area of redness will develop within twelve hours in positive reactors. This is the *Dick* test.

Strains of group A streptococci may be segregated into numbered types by serological methods devised by Griffith and Lancefield. Antibacterial immunity is type specific, probably long lasting, and protects against subsequent reinfection by a strain of the same type. None of the antibodies which develop in response to stimulation by the extracellular substances described above seems to influence the parasitism of human beings by group A streptococci.

History. Sydenham is often stated to have described scarlet fever, but the early accounts are inadequate and inexact. Certainly this disease, the intimately related tonsillitis and pharyngitis with out a skin rash, and erysipelas had been recognized for many years before the discovery of *Streptococcus pyogenes* by Rosenbach in 1884. Significant understanding of streptococcal infections began with the discovery by Schottmüller in 1903 that certain strains produced hemolysis on blood agar. Brown in 1919 defined this reaction in greater detail and coined the descriptive terms that are still in use.

The streptococcal etiology of scarlet fever and tonsillitis was quite well established by 1895. Certain Russian investigators had immunized large numbers of children with various streptococcal products and treated many cases of scarlet fever with antiserum in the first years of this century. All of this information was discarded throughout most of the world for many years. It was held that the hemolytic streptococci present in the throats of patients with scarlet fever were secondary invaders and that tonsillitis could be caused by a large number of different bacteria.

The re-establishment of the streptococcal etiology of scarlet fever by the Dicks and Dochez led to renewed interest in the whole subject and Bloomfield clearly defined the streptococcal etiology of nearly all cases of tonsillitis. The unravelling of the whole spectrum of streptococcal respiratory infection and the important non-suppurative complications has been accomplished since 1935. This was stimulated especially by the serological classification of the organism by Lancefield and Griffith and by the great epidemics of streptococcal disease in the armed forces in World War II which supplied an enormous volume of clinical material. The careful studies of these disorders in children by Powers and his associates have also been most provocative with respect to the mechanism of the different patterns of streptococcal disease at different ages.

**Epidemiology.** Group A hemolytic streptococci are the only significant cause of nonpneumonic bacterial respiratory infec-

tions in children over the age of five and in adults. There is a surprising lack of information in regard to the etiology of this type of infection in infants and young children.

Nearly all respiratory infections in all age groups are caused by filterable viruses. The proportion of streptococcal infections varies with the season of the year and the geographical location. In the United States the peak incidence is between December and May. The North Atlantic states, a broad area around the Great Lakes and belts running north and south along both sides of the Rocky Mountains appear to be the areas most propitious to the spread of group A streptococci.

Approximately 10 per cent of nonpneumonic respiratory infections that are sufficiently severe to bring the patient to the attention of a physician are due to hemolytic streptococci. If all such respiratory illnesses in a middle class population are considered it is found that only about 2 per cent are the result of infection by these organisms.

In any season in any community the same serological types of group A hemolytic streptococci are responsible for all varieties of disease caused by these organisms. There is no specific streptococcus of scarlet fever, sore throat, erysipelas, cellulitis or puerperal sepsis, although certain strains at certain times seem quite incapable of producing a rash. It is not known whether this is a fixed characteristic of these organisms.

Quantitatively upper respiratory infections including scarlet fever, pharyngitis and tonsillitis are the only important forms of group A streptococcal infection. Illness in these categories occurs most frequently in children from five to fifteen years of age, but younger and older persons are highly susceptible to infection.

Transmission of group A streptococcal infections usually occurs as the result of direct contact between infected persons or healthy carriers and susceptible persons. Significant extra-human or animal reservoirs of these organisms do not exist although many outbreaks due to contamination of an article of food, often milk, have occurred. The incubation period is two to three days.

Children among whom infection is commonplace and healthy carriers are abundant are primarily responsible for the spread of streptococcal disease. The introduction of an untreated infected five-year-old into a family will be followed by infec-

patient should receive either tetracycline chlorotetracycline or oxytetracycline in doses of 0.5 gm every six hours until the temperature falls to normal. The dosage may then be reduced to 0.5 gm twice daily but treatment should be continued for at least another three days. If side reactions such as nausea, vomiting and diarrhea occur it may be necessary to reduce the amount of drug or to discontinue therapy entirely.

Symptomatic therapy may include codeine in doses of 0.03 to 0.06 gm to control cough. Inhalations of steam are helpful in relieving soreness and dryness of the upper respiratory passages. Salicylate compounds should be used cautiously since some patients respond badly to their use. When the disease is severe with respiratory embarrassment oxygen therapy is usually indicated. During convalescence it is recommended that the patient be kept at bed rest for several days after the temperature

is normal since early ambulation may be followed by symptoms of weakness, lassitude and easily induced fatigue.

## Streptococcal Infections

### Introduction

Streptococci commonly cause disease particularly of the respiratory tract in man. The most simple classification of these organisms and the one most useful for clinical purposes is based on their action on blood agar plates. Beta hemolytic streptococci are those able to produce a completely clear zone around the colony. The term alpha hemolysis indicates that there is hemolysis circled by a green ring surrounding the central colony. This appearance characterizes the organisms known as *Streptococcus viridans*. Many streptococci are completely nonhemolytic.

The alpha hemolytic and nonhemolytic streptococci are normal inhabitants of the upper respiratory tract of man from a few hours after birth until death and may also be recovered from the feces. Many require reduced oxygen tension for initial isolation. Infection by these streptococci is unusual except in bacterial endocarditis and in suppurative disease arising by direct extension of the organisms from the upper respiratory tract, colon or female genital organs. In these circumstances such disorders as paranasal sinusitis and cerebral or intra-abdominal abscesses may develop.

The most important of the streptococci are those that produce beta hemolysis on

blood agar. Organisms having this characteristic may be segregated into lettered groups by the use of a precipitin reaction described by Lancefield. Those of the greatest significance in human disease are the members of group A. These organisms often parasitize and cause disease of the respiratory tract of previously healthy persons.

Hemolytic streptococci of the other groups are less important. Nonhemolytic or alpha hemolytic varieties of many have been described following the original studies of Lancefield that were carried out with hemolytic strains. Organisms of groups B and D may cause bacterial endocarditis and infection of the urinary tract. Members of group D are the enterococci, the common streptococci present in the normal colon. Streptococci of the other lettered groups C, E, F, G, H, K, L, M and N are most often discovered in the flora of the upper respiratory tract and rarely cause human disease.

Group A streptococci form an extraordinary variety of extracellular substances many of which stimulate an immune response in the infected individual. Measurement of certain of these antibodies such as antistreptolysin O, antistreptokinase and antihyaluronidase are of importance in the study of streptococcal disease and its complications. The erythrogenic toxin is

complication which develops after the first week is likely to be the result of a reinfection and a different type will be recovered from the purulent exudate.

Bacteremia was once observed rather frequently during the course of streptococcal respiratory infection and was often associated with metastatic lesions in the joints, bones and elsewhere. Such cases are now almost unknown even if antimicrobial therapy is withheld. Similarly there has been a nearly complete disappearance of group A streptococcal meningitis. Pneumonia has always been a surprisingly uncommon complication of streptococcal upper respiratory infections.

Tender cervical adenitis is regularly present and is not to be regarded as a complication unless the lymph nodes become very large and suppuration is imminent.

All of the various suppurative streptococcal complications may be prevented by early and adequate antimicrobial therapy. Response to similar management is excellent if any should develop in an untreated patient.

**Nonsuppurative Complications** Antimicrobial therapy has made the management of acute hemolytic streptococcal infection of all types a simple matter. Suppurative complications are readily prevented by appropriate treatment and are in fact rarely seen in the United States today. For this reason the greatest interest in disease caused by these organisms has centered recently about the poststreptococcal sequelae that are included in the group of nonsuppurative complications.

Most important of these are *rheumatic fever*, *glomerulonephritis* and *mesenteric adenitis*. All occur one to three weeks after the complete subsidence of the initial streptococcal illness. In none is there evidence of dissemination of the organism from the throat or other area of primary infection to the affected internal organs nor does the pathological anatomy of these processes suggest a suppurative disorder.

There can be little doubt any longer that all of these disorders are complications of group A hemolytic streptococcus infection but their pathogenesis is poorly understood. It is now evident that strains of only a few types of group A hemolytic streptococci are able to cause glomerulonephritis but nearly all strains are rheumatogenic. Many investigators believe that an inappropriate immunological reaction is responsible for these diseases and that this may well require repeated exposure of the individual over some period of time to different

types of group A streptococci. It is noteworthy that rheumatic fever and nephritis are rare complications of streptococcal infection before the age of four to five years.

Approximately 3 per cent of streptococcal infections which have occurred in well studied epidemics have been followed by the development of rheumatic fever. The incidence of glomerulonephritis in outbreaks caused by nephritogenic strains of streptococcus has been much greater.

All of the recognizable clinical manifestations of rheumatic fever may be prevented by adequate treatment of the initial streptococcal illness with an appropriate antimicrobial agent. It is not yet known whether this can also be accomplished for glomerulonephritis but preliminary study suggests that the incidence of this disease will also be reduced.

**Treatment** The management of the various streptococcal illnesses should include those general measures that are applied in all acute infections. Bed rest, light or liquid diet if angina is present and severe and adequate but not excessive fluid intake are indicated. Gargles are of little value but considerable relief of sore throat may be obtained by the use of hot saline throat irrigations. Acetylsalicylic acid in a dose of 0.3 to 0.9 gm every three to four hours is often of great symptomatic benefit.

Most important is the prompt institution of appropriate antimicrobial therapy which has four goals: (1) the prompt control of the acute suppurative process in the respiratory tract or elsewhere; (2) the prevention of suppurative complications; (3) the prevention of nonsuppurative complications; and (4) the elimination of the carrier state and the prevention of transmission of the organism to others. The third and fourth will be fully attained only if the organism is permanently eradicated from the tissues. This can best be accomplished by the administration of penicillin and less well by the use of erythromycin and tetracyclines. Sulfonamides are not effective and novobiocin is too toxic for use in treatment of streptococcal infection. No examples of penicillin, erythromycin or tetracycline resistant group A streptococci have been described. It is essential that full doses be given over a period of ten days regardless of the drug used.

Penicillin is preferred and should be used in every case unless the patient is known or believed to be sensitized to it. It should be administered in one of three ways if an uncomplicated respiratory infection is under treatment:

tion of more than half of his siblings and a significant number of adults in the household. Hamburger and his associates have shown that a patient or healthy carrier who harbors hemolytic streptococci in the nose is most likely to contaminate the environment with these organisms and to transmit disease.

The problem of control of hemolytic streptococcal disease is complicated by the fact that a very large proportion of infections by these organisms are either exceedingly mild or completely inapparent. Persons with this type of illness are fully capable of disseminating the streptococci but will not come under the care of a physician who could apply modern chemotherapy, eradicate streptococci from the pharyngeal tissues and eliminate the possibility of transmission of disease.

**The Nature of Streptococcal Respiratory Infection.** When group A streptococci parasitize the upper respiratory tract of human beings they multiply most freely in the lymphoid tissue of the pharynx and the tonsils. The subsequent illness is presumably the result of the release of substances at this site which are injurious to the local tissues and which produce systemic disturbances. The nature of the response to infection is conditioned by the age of the subject and his previous exposure to streptococci.

Group A streptococcal respiratory infections in infants and small children lack an acute and well defined onset, have rhinorrhea as a dominant manifestation, are rarely associated with high fever and run a protracted and indeterminate course. The physical signs in the throat are nondescript and usually do not permit an accurate clinical diagnosis. Suppurative complications such as otitis media and cervical lymphadenitis occur frequently. A rash is rarely observed.

The disease in older children is quite different. The onset is often acute with high fever, sore throat is the predominant symptom and typical exudative tonsillitis and pharyngitis are usually present. A rash (scarlet fever) is often discovered. Suppurative complications decline in frequency with advancing age. Adults experience an illness much like that of older children except that a rash or suppurative complications of any kind rarely occur.

Powers and his associates proposed and subsequent investigations have supported but not established the hypothesis that these changing patterns of streptococcal illness which occur with advancing age

are the result of repeated infection by different types of group A streptococci rather than simple maturation of the host. It has been suggested that an immunological mechanism involving the development of hypersensitivity to certain of the products of the streptococcus may be responsible.

**Diagnosis of Streptococcal Infection.** The precise diagnosis of hemolytic streptococcal infection requires measures beyond clinical examination and simple laboratory procedures. Of greatest importance and presenting the greatest difficulties is the recognition of streptococcal upper respiratory infection, especially in young children. Bacteriological study of material obtained from the nasopharynx is very often essential.

Swabs should be passed through the mouth under direct vision using a good light and rubbed over the tonsils and posterior pharynx before any antimicrobial therapy is administered. The swab should be streaked directly with a minimum of delay on sheep blood agar plates of low dextrose content. After incubation the number of hemolytic streptococci present should be recorded in a roughly quantitative manner. These organisms will be very numerous in nearly all cases if they are the cause of the infection. The presence of a few does not provide convincing evidence that they are responsible for the illness because 5 to 10 per cent of the general population are nasopharyngeal carriers of these organisms. Their absence may be regarded as excluding streptococcal disease. Serological grouping and typing of the isolated organisms is not necessary for routine clinical study.

Additional information may be obtained in selected cases when indicated by serial measurement of antibody titer (antistreptolysin O) over a period of four to six weeks. A significant increase provides positive evidence of the presence of a hemolytic streptococcal infection.

**Suppurative Complications.** Direct extension of the hemolytic streptococcus from the locus in the throat to the surrounding tissues may result in certain suppurative complications. Paranasal sinusitis, otitis media, mastoiditis, suppurative cervical adenitis and impetigo are the most common and will occur most frequently in untreated children less than four years old.

It has been demonstrated that otitis media occurring early in the course of streptococcal respiratory infection is caused by the same serological type that was present in the throat at the onset. A similar

## Hemolytic Streptococcal Sore Throat

The general term "hemolytic streptococcal sore throat" is often used to describe the various forms of nonpneumonic group A streptococcal respiratory infection. Among these scarlet fever and tonsillitis are distinguishable entities. It should be emphasized that there is a spectrum of disorders in this broad category which depend upon the age of the patient, his previous experience with group A streptococci and the presence or absence of tonsils and which often may not be differentiated readily from one another.

A rash is present in only a small percentage of clinically recognizable streptococcal infections. The frequency will vary

with the age of the affected population and the scarlatinogenic potentialities of the infectious agent. If the enormous numbers of mild atypical and inapparent streptococcal illnesses which are rarely associated with erythema are considered, it becomes apparent that scarlet fever is an unusual manifestation of streptococcal respiratory infection in the United States.

Patients who develop a rash are on the average more sick than those who have tonsillitis or pharyngitis without a rash, but there is substantial overlapping in the degree of severity of illness in the two groups. There will be no difference in the incidence of suppurative or nonsuppurative complications in persons of comparable age.

Erythema is unusual before the age of three and in adolescents and adults. It cannot be emphasized too strongly that antitoxic immunity against the erythrogenic toxin confers no protection against subsequent infection by other types of group A streptococci.

## Acute Tonsillitis and Pharyngitis

Acute tonsillitis and pharyngitis are inflammatory processes of the lymphoid tissue of the pharynx usually caused by group A hemolytic streptococci. A form of nonbacterial tonsillitis and pharyngitis occurs probably caused by an adenovirus which may be most difficult to distinguish from streptococcal disease. It often occurs in epidemics (see page 9).

**Morbid Anatomy and Pathology** There is a ring of lymphoid tissue encircling the pharynx which includes the palatine and lingual tonsils and the adenoids. Similar tissues are situated widely over the pharyngeal walls in smaller masses. It is believed that all of these areas are involved in most cases of streptococcal pharyngitis. In many instances the faucial tonsils become particularly swollen and covered with a purulent exudate and exudative tonsillitis is the result.

The essential lesion is a suppurative one with inflammation and swelling of the affected areas and with outpouring of leukocytes and fibrin. Very often they combine to form an extensive exudate.

**Etiology** The bacterial form of exudative tonsillitis is usually caused by group A hemolytic streptococci. Rare infections by strains of groups C and G have been described but there is no evidence that pneu

- 1 Benzathine penicillin G as a single intramuscular injection of 900 000 to 1 200 000 units
- 2 Oral penicillin four doses daily for ten days of 200 000 (125 mg) to 400 000 (250 mg) units of penicillin V or G. The latter should be contained in a buffered tablet
- 3 Procaine penicillin with aluminum monostearate as a single intramuscular injection of 600 000 units every other day for three doses

Patients with more serious streptococcal infections such as severe tonsillitis, scarlet fever, those of the skin or lung, or a suppurative complication of an ordinary respiratory infection should receive 600 000 to 900 000 units of procaine penicillin per day for several days until the illness is obviously subsiding, when a shift to a single dose of benzathine penicillin or to oral penicillin may be made.

The response of extrapharyngeal suppurative complications of streptococcal infection to penicillin is good and recovery without surgical intervention is the rule, with one exception. Sterilization of the local abscess in well established suppurative cervical adenitis is most difficult. Incision and drainage is usually required in such cases unless spontaneous rupture occurs.

When penicillin is contraindicated because of hypersensitivity, it is proper to employ erythromycin by mouth in a dose of 250 mg four times a day for at least ten days. Similar amounts of one of the tetracycline drugs may also be used, but this is a less satisfactory regimen. Severely ill patients may well receive 500 mg of erythromycin twice daily intravenously for a short time until it is certain that the drug will be accepted and absorbed when given by mouth. Sulfonamides should not be used in the treatment of hemolytic streptococcal infections.

**Prophylaxis.** There are no simple preventive measures which may be applied to the control of streptococcal infections in the population at large. Isolation and other standard public health procedures must always fail because of the huge numbers of carriers and missed cases, particularly among children. Many communities in the United States have abandoned quarantine of scarlet fever and other streptococcal diseases as fruitless.

It is important to remember that hemolytic streptococci will have disappeared from the throat within a few hours after the administration of penicillin or another effective antimicrobial agent. If treatment

is prolonged adequately the carrier state will be eradicated in nearly all infected persons and carriers. Tools are thus readily at hand for the prevention of transmission of streptococcal disease by recognizably infected persons or carriers.

It is often desirable to prevent group A streptococcal infections in selected persons who are well. These are persons who have had rheumatic fever or rheumatic heart disease and closed groups in schools and similar establishments and in the armed forces who are experiencing an outbreak of streptococcal disease.

Unfortunately, no form of immunization is of avail. Tonsillectomy has been employed prophylactically in the past but is now known to be useless for this purpose since it does not prevent infection by hemolytic streptococci. Subsequently acquired streptococcal respiratory illnesses may be less severe, but the frequency of occurrence of nonsuppurative complications is not reduced.

**Chemoprophylaxis** has proved to be highly effective and may be attained by one of three regimens listed below in order of their apparent efficacy and practicability.

- 1 Benzathine penicillin G in a single injection of 1 200 000 units will provide protection for about thirty days.
- 2 Sulfonamide in daily administration by mouth of 10 gm of sulfadiazine or one of the other sulapyrimidines provides satisfactory prophylaxis but failures will occur. Toxic reactions may be observed during the first sixty days of continuous treatment.
- 3 Oral penicillin in daily administration of 200 000 (125 mg) units of penicillin G has been employed widely for prevention of streptococcal infection but failures have been as frequent as with sulfonamide therapy. The same amount given twice daily is believed to be highly effective but the multiple doses create an overly complicated regimen. There is insufficient experience with the better absorbed penicillin V to permit recommendations as to its proper use in streptococcal prophylaxis.

Little is known of the possible role of the other potentially effective antimicrobial agents for this purpose and they should not be so used.

 Breese B H and Disney F A. Penicillin V. *Treat*

pharynx for long periods after recovery if antimicrobial therapy has not been employed. The more detailed and elaborate the cultural procedures the more frequently they may be discovered and over longer periods of time. The usual simple techniques will recover them in about 70 per cent of adults during the fourth week. Their presence may be regarded as a public health hazard but does not prejudice the health of a patient who has recovered from a streptococcal illness.

**Complications.** Suppurative and nonsuppurative complications may follow untreated streptococcal tonsillitis and pharyngitis. The former are unusual except in small children and the latter are rare in patients less than five years of age (see Introduction). Both may be prevented by appropriate antimicrobial therapy.

**Treatment.** Adequate and appropriate antimicrobial therapy should be administered whenever the diagnosis of group A hemolytic streptococcal tonsillitis or pharyngitis is reasonably certain on clinical and laboratory grounds (see Introduction). Every effort must be made to avoid the indiscriminate treatment of the more common viral respiratory illnesses many of which may be difficult to distinguish from streptococcal disease.

## Scarlet Fever

**Definition.** Scarlet fever is a form of group A hemolytic streptococcal infection of the upper respiratory tract. The disease is similar to acute tonsillitis and pharyngitis caused by these organisms with the addition of an exanthem and an enanthem. The etiology and epidemiology of the disease are discussed in the Introduction.

**Pathogenesis.** The pathogenesis of the skin rash in scarlet fever has been extensively investigated but no final conclusions have been reached. One group of investigators has believed that the erythrogenic material has a direct toxic action on the skin which is neutralized by antitoxin. Others have noted that infants are Dick

negative even though no antitoxin is demonstrable in their serum and their mothers are Dick positive. These and other observations have suggested that reactivity to the rash toxin may be of an allergic type acquired by previous contact with the hemolytic streptococcus. Little is known of the pathogenesis of the other manifestations of scarlet fever. The changing nature of streptococcal disease from infancy to adulthood which has been described in the Introduction strongly suggests that an alteration of general and local tissue reactivity occurs as the result of successive apparent or inapparent infections by hemolytic streptococci.

**Morbid Anatomy.** The essential lesion in scarlet fever is the suppurative process in the nasopharynx which is common to all forms of hemolytic streptococcal upper respiratory infection. The dermal lesion is a hyperemia which is the result of toxic injury of the vascular endothelium leading to atony and dilatation. There are also edema of the skin and aggregations of lymphocytes and monocytes particularly around the hair follicles. Inflammatory exudate accumulates within the middle layers of the epidermis and accelerated keratinization occurs in this area. This alteration in the skin leads to desquamation as the outer layer separates from the keratinized intermediate zone.

**Symptoms and Signs.** Scarlet fever except for the presence of a skin rash closely resembles the other forms of hemolytic streptococcal upper respiratory disease in comparable age groups. The onset is usually abrupt often with a chill or chilly sensations. Headache, nausea and vomiting occur frequently. Sore throat is the principal localizing symptom and is rarely absent. It may be so severe that swallowing of even liquids is agonizing.

In typical cases the mucous membrane of the throat is fiery red, the intensity of the color usually seen in streptococcal sore throat being enhanced by the enanthem. Otherwise the signs present in this area are identical with those previously described in the section on tonsillitis and pharyngitis. The distinctive signs are limited to the pharynx, the cervical lymph nodes and the skin. The tongue may be bright and the papillae large (raspberry tongue) or coated with the red papillae protruding (strawberry tongue). These manifestations of the disease are rarely seen in adults. Tender anterior cervical adenitis is regularly present even if the disease is mild. Atypical cases are common.

cocci micrococci or other organisms will cause this syndrome in older children or adults. There is an amazing paucity of information about the etiology of this type of respiratory infection in infants and young children.

Hemolytic streptococci are the only significant bacterial cause of nonexudative pharyngitis. Many viral infections may mimic this clinical state making the study of upper respiratory infection without bacteriological control most difficult.

**Symptoms** The onset of streptococcal tonsillitis and pharyngitis in older children and adults is usually quite abrupt but varies greatly in intensity. Usually the first symptom is sore throat which may remain mild or rapidly become severe with great pain on swallowing. The soreness may be unilateral or bilateral and is characteristically at the sides of the neck under the angles of the jaw. Many patients with viral respiratory infections also have sore throat but careful questioning often reveals that the symptom is localized to the anterior neck over the trachea and larynx.

Streptococcal respiratory infection is not accompanied by significant cough or by coryza. The presence of either of these manifestations should suggest a different etiological diagnosis. Rhinorrhea does occur especially in young children who frequently develop suppurative sinusitis.

Very often there are chilly sensations or a chill near the onset with the appearance of fever which may be trivial or rise to 105° F. Head back and muscle aching will be present in such circumstances.

**Signs** Proper diagnosis of respiratory infection requires careful examination of the pharynx using a good light. The typical signs in a person whose tonsils are intact are most characteristic. The anterior pharyngeal tissues are swollen, engorged and fiery red. Often the uvula will resemble a red iridescent sac two to three times its normal size. The tonsils are greatly enlarged, may nearly meet in the midline and are covered with a thick creamy exudate which may be readily scraped off with a tongue depressor or swab. That part of the posterior pharynx which is visible will also be red, swollen and covered with exudate. The anterior cervical lymph nodes at the angles of the jaw are swollen and tender in nearly all cases. The clinical picture may be very similar if the tonsils have been removed except for the absence of the signs attributable to these organs.

Many examples of streptococcal tonsillitis and pharyngitis do not present the

complete picture just described. Exudate may be present in very small amount or absent in less severe cases even though the tonsils are intact and edema may be slight. Often in such cases the most useful signs will be the presence of redness of the throat and tender lymph nodes at the angles of the jaw.

**Laboratory Findings** Total leukocyte counts greater than 12,000 per cu mm are the rule in typical hemolytic streptococcal tonsillitis and pharyngitis. Unfortunately there may be no abnormality in the less severely ill patients who present the greatest difficulties in clinical diagnosis. The erythrocyte sedimentation rate is usually quite rapid and the C reactive protein test is strongly positive. Cultural study of the pharyngeal flora (see Introduction) is an invaluable guide to precise diagnosis.

**Differential Diagnosis** Streptococcal tonsillitis in its typical form need be differentiated only from diphtheria, nonbacterial exudative tonsillitis and infectious mononucleosis.

Nonexudative tonsillitis and pharyngitis caused by hemolytic streptococci may resemble particularly in children certain of the nonbacterial respiratory illnesses. Accurate clinical diagnosis even with great experience is most difficult. The presence of marked sore throat, leukocytosis and tender anterior cervical adenopathy should weigh the diagnosis toward streptococcal disease. Cough, coryza and rhinorrhea (in adults) make a nonbacterial disorder more likely. Cultural examination of the throat is often necessary.

**Course** The course of untreated hemolytic streptococcal tonsillitis and pharyngitis in older children and adults is benign. Seventy per cent of patients are afebrile within seventy-two hours after onset but sore throat, abnormal signs in the pharynx and tender adenitis persist for two or three days after the return of the temperature to normal. The latter event often occurs by crisis.

The whole process is shortened by appropriate antimicrobial therapy by twenty-four to forty-eight hours, the most dramatic effect being on the course of the fever and the least on the abnormal physical signs.

Leukocytosis persists in more than one half of untreated patients for a week or more but disappears more quickly after the institution of antimicrobial therapy. The erythrocyte sedimentation rate returns to normal in 80 per cent of patients by the third week.

Hemolytic streptococci persist in the

fever may resemble that of diphtheria. No rash is seen in the latter disease but it must be remembered that the two may occur simultaneously. The erythema of rubella (German measles) and rubeola (measles) must be distinguished from that of scarlet fever. Infectious mononucleosis with angina and a rash may easily be mistaken for scarlet fever if appropriate cultural and hematological studies are not carried out. The erythematous rashes of drug sensitivity are often similar to the dermal lesion of streptococcal disease. The absence of other characteristic symptoms and signs of scarlet fever should permit their recognition in other than the most unusual case.

**Prognosis.** Scarlet fever in the United States at the present time is a relatively mild disease and the prognosis without antimicrobial therapy is uniformly good. Suppurative complications are common in younger children but are well controlled by proper treatment. Serious late nonsuppurative complications must be anticipated during convalescence regardless of the severity of the initial illness if appropriate antimicrobial therapy has not been administered. Rheumatic fever is most likely to supervene in patients with a past history of this disease.

**Treatment.** The treatment of scarlet fever is the same as that recommended for other streptococcal infections (see Introduction). If the disease is severe 600 000 to 900 000 units of procaine penicillin should be administered daily for the first two or three days.

In the past specific antitoxin was employed. This involved the injection of an antiserum prepared by the immunization of horses with filtrates of group A hemolytic streptococci or of convalescent human serum. The advent of potent antimicrobial drugs has made serotherapy largely unnecessary. The hazards accompanying the administration of foreign protein and the discomfort of the associated serum sickness suggest that horse serum antitoxin should rarely be used in the treatment of scarlet fever. If indicated 15 000 to 30 000 units are to be administered intravenously or intramuscularly with the usual precautions. Convalescent human serum should not be used because of the danger of serum hepatitis.

The toxic and systemic aspects of scarlet fever are not quickly ameliorated by the administration of penicillin. Improvement does begin shortly after this agent is ad-

ministered. It is well established within forty-eight hours and may confidently be expected to continue to eventual recovery by the fourth day. It is reasonable to conclude that serum therapy should be reserved for those rare cases in which extreme toxicity suggests that a fatal outcome might ensue before the effect of parenteral penicillin could manifest itself or for those patients in whom this agent has been given for forty-eight hours without evidence of benefit.

**Prophylaxis.** The prophylaxis of scarlet fever is that of other group A hemolytic streptococcal infections and is discussed in the Introduction. Active immunity to the erythrogenic toxin may be attained in Dick-positive persons by repeated injections of increasing amounts of the active material. This procedure is not recommended since protection is conferred only against the development of a rash and not against infection by hemolytic streptococci. Furthermore reactions during immunization are common and often severe.

## Erysipelas

**Definition.** Erysipelas is an acute group A hemolytic streptococcal infection of the skin which usually involves the face and head but may affect any area of the body.

**History.** Erysipelas has been known since very ancient times. There was a great outbreak of the facial form of the disease in the Union Army during the Civil War during which more than 25 000 cases were reported to the Surgeon General.

The communicability of the infection was recognized before the isolation of the etiological agent from the skin of sick persons by Fehleisen in 1882. He transmitted the illness to other human beings by the experimental inoculation of pure cultures of streptococci.

**Etiology and Pathogenesis.** Group A hemolytic streptococci are the only significant organisms responsible for erysipelas al-

particularly in persons in whom the tonsils have been removed. Tonsillar and pharyngeal exudate, edema and redness may be minimal or absent.

The rash usually appears on the second day. It consists of a diffuse bright scarlet erythema with many points of deeper red. The distribution is variable but the trunk and inner aspects of the arms and thighs are most often affected. In many cases the rash is well marked only in the axillae and groins. The face is flushed and red but a pale area, the *circumoral pallor*, is often seen around the mouth. The palms and soles are not erythematous. Petechiae and occasionally ecchymoses are observed especially in severely ill patients. The application of a tourniquet to the arm for five minutes will be associated with the appearance of large numbers of petechiae distal to the obstruction in nearly all cases. This is *Rumpel-Leede's sign*; it is not specific for scarlet fever.

**Course.** The rash reaches its height as do the other manifestations of the disease on the third or fourth day after which there is the beginning of defervescence. The erythema disappears by the sixth to ninth day in association with a return of the temperature and the throat to normal.

Desquamation begins as a fine scaling of the face and body which is usually completed during the second week. About this time the extensive and characteristic desquamation of the palms and soles starts and continues for one to two weeks.

The course and clinical features of scarlet fever vary greatly with the severity of the disease. Many mild cases are observed in which constitutional symptoms and sore throat are minimal, fever is low grade and of short duration and the rash is evanescent. A florid eruption is sometimes seen in persons in whom all other evidences of the disease are slight, indicating that the reaction to the erythrogenic toxin *per se* is not primarily responsible for the systemic manifestations of scarlet fever.

As the disease becomes more severe there is a general increase in the intensity of all symptoms and signs. The maximum temperature in individual cases of the more severe forms will be 101 to 106 F. The angina will be distressing and marked prostration evident. The rash will usually be prominent but severe cases with little erythema are often seen.

**Malignant Scarlet Fever.** A toxic or malignant type of scarlet fever was regularly described in earlier studies of this disease. A fulminating course was associated with

delirium, collapse and death—often within forty-eight hours. The short duration of the disease did not permit the development of a typical erythema but hemorrhages in the skin were observed. Such cases in which death occurred quickly without dissemination of the streptococci from the local focus in the throat are now rare. Similarly septic scarlet fever or streptococcal sore throat with bacteremia, metastatic suppuration in the joints and elsewhere and a prolonged and often fatal course has disappeared in properly treated cases.

**Complications.** The complications of scarlet fever are those common to all forms of hemolytic streptococcal upper respiratory infection with or without a rash and are of two types: the suppurative and the nonsuppurative. Both have been described in the Introduction.

**Relapse.** Relapse is unusual in untreated scarlet fever but reinfection with a new serological type of hemolytic streptococcus may occur at any time during convalescence and lead to an apparent exacerbation of tonsillitis and pharyngitis. Recovery from scarlet fever is usually associated with a permanent immunity to the rash toxin and second attacks are rare. It must be emphasized again that protection against subsequent infections by other types of hemolytic streptococci is not conferred and episodes of tonsillitis and pharyngitis occur frequently in persons who have had scarlet fever.

**Diagnosis.** The recognition of scarlet fever in its characteristic form is not difficult. The presence of angina, tonsillitis, anterior cervical adenitis and erythema permits a clinical diagnosis in many instances. Cultural examination of material obtained from the nasopharynx is essential in atypical cases (see Introduction).

The injection of 0.1 ml. of scarlet fever antitoxin or of 0.2 to 0.3 ml. of convalescent human serum into an area where the rash is florid will be followed by blanching around the site of injection in eight to twelve hours. This is the *Schultz-Charlton reaction*. It is inadvisable to perform this test with human serum because there is substantial danger of transmission of serum hepatitis. Streptococcal antitoxin is no longer readily available. Usually clinical and bacteriological study suffice for diagnosis.

**Polymorphonuclear leukocytosis** is the rule in moderately severe and severe scarlet fever but is often absent in mild cases.

The local pharyngeal lesion in scarlet

**Complications** The most important complication of untreated facial erysipelas is local abscess formation in some part of the involved skin which develops in 5 to 10 per cent of these patients. Rheumatic fever is an extraordinarily infrequent complication of erysipelas but glomerulonephritis is less so. Untreated patients may relapse a few days after apparent recovery. It is probable that all of these complications can be prevented by adequate treatment but detailed studies of large numbers of cases of erysipelas managed by the use of modern antimicrobial agents are not available.

Persons who have suffered an attack of erysipelas are quite likely to undergo similar illnesses at irregular intervals throughout their lives.

**Prognosis** Untreated erysipelas was highly lethal for children less than two and persons over sixty years of age and in those with serious underlying debilitating disease. Generalized sepsis with bacteremia and widespread dissemination of the infection was the usual sequence of events. Prompt and early treatment prevents both the lethal and nonlethal complications of the disease in all age groups. The mortality rate must now be extremely low.

**Treatment** Treatment of erysipelas should be that recommended (see Introduction) for severe hemolytic streptococcal infection. The application of petrolatum two or three times a day or of cold normal salt solution to the involved skin often increases the comfort of the patient during the first two days of treatment before the infectious process subsides.

The temperature returns to normal within forty-eight hours after the initiation of effective chemotherapy and the spread of the skin lesion stops abruptly. Several days usually elapse before the skin returns to normal.

## Peritonsillar Abscess

### (Quinsy Sore Throat)

Peritonsillar abscess is a complication of hemolytic streptococcal sore throat in which suppuration extends through the capsule of the palatine tonsil into the loose connective tissue of the neck.

**Etiology** The etiology of peritonsillar abscess is unknown. Hemolytic streptococci are not regularly recovered from the purulent exudate. The streptococcal infection may damage the tissues permitting invasion by other organisms. It is probable that anaerobic gram-negative bacilli of the Bacteroides group and anaerobic non-hemolytic streptococci are involved in many cases. The disease has become very uncommon since the introduction of antimicrobial therapy of tonsillitis.

**Symptoms and Signs** The abrupt increase of soreness and swelling of the neck on one side during the course of an illness associated with sore throat is the most important symptom of peritonsillar abscess. This change in the course of the illness usually is accompanied by increased fever and malaise. Swallowing may become impossible; the neck will bend toward the affected side and eventually it may be impossible for the patient to open his mouth.

On examination the affected tonsil and anterior pillar are greatly swollen and may protrude to the midline of the throat. The cervical lymph nodes on the same side are also greatly enlarged and tender. Eventually a fluctuant area can be palpated by the gloved finger in the supratonsillar fossa.

**Complications** The most important complications are those in which the suppurative process extends further into the neck and those associated with septic thrombophlebitis of the cervical veins with bacteremia and dissemination of the infection.

Aspiration of purulent material from a spontaneously ruptured abscess and development of pneumonia or lung abscess may also be a hazard.

**Treatment** The treatment should be that outlined for severe and complicated hemolytic streptococcal infections (see Introduction). The whole process will subside without drainage if therapy is instituted early. If not liquefaction of the affected tissues will occur. The purulent collection may rupture into the throat spontaneously or the fluctuant area may be incised through the mouth. The latter procedure is preferable and is usually followed by prompt improvement.

though an occasional case caused by a strain of group C has been recognized

The precise way in which the bacteria are introduced into the skin in primary facial erysipelas has not been determined. Large numbers of group A streptococci are quite constantly present in the nasopharyngeal flora of patients with early erysipelas. It may be that the primary infection is a nasopharyngitis from which the organism is transferred to the skin. This situation prevails in sporadic streptococcal impetigo which is such a common complication of hemolytic streptococcal respiratory infection in small children.

After reaching the face the streptococci may enter the skin through minute abrasions that are not recognizable after the disease is well established. This hypothesis presumes that the organisms in the skin have been derived from the patient's own respiratory tract. In surgical and wound erysipelas it is probable that streptococci are introduced into the traumatized areas from external sources, usually the nose and throat of attendants and other patients.

**Epidemiology** The epidemiology of facial erysipelas must be that of group A hemolytic streptococcal infection but the affected age groups are different. This disease when large numbers of cases were observed in the past was rather common in infancy, rare between the ages of six and thirty and was predominantly a disorder of middle age. This is precisely the reverse of the age distribution of streptococcal respiratory infection. There has been no explanation for this discrepancy in age distribution.

**Pathology** Erysipelas is an acute inflammation of the skin associated with the presence of hemolytic streptococci in the lymph channels. The organisms spread through these vessels to involve adjacent tissues. They may be isolated easily from the advancing border of the lesion by appropriate methods.

**Natural History** The febrile onset of erysipelas is usually abrupt and is often associated with a shaking chill. A history of a preceding acute or subacute upper respiratory infection is obtained in approximately one third of adult cases and more frequently in infants.

The local lesion is not infrequently minimal and may be overlooked during the first twenty-four hours of illness. Usually however there is a definite zone of redness and edema of the skin which can be readily discovered very early in the disease. It most

frequently involves the bridge of the nose in the facial form and is found around a surgical incision, traumatic wound area of dermatitis or the newly severed umbilical cord in the extrafacial types of the disease.

Facial erysipelas is usually self limited if no antibacterial therapy is administered. Under these circumstances the temperature remains at a high level for four to ten days (mean of seven and one half days) and then falls by lysis or crisis. During this interval the local process involves a large part of the face. As the lesion develops and spreads from the central focus the skin is red, hot, edematous and glistening. Blebs are frequently formed. The advancing edge is sharply defined and slightly elevated. Great swelling occurs when the infection involves the eyelids.

The disease may involve one or both sides of the face and usually remains active and spreading until the cheeks and eyelids are affected. Very often the inflammatory process does not extend over the bony prominences and is limited to the area between the mandible, the malar eminence and the hair line. In certain cases the ear is included but spread to the scalp and trunk is rare except in infants.

Untreated erysipelas of the trunk or extremities which usually occurs in infants or persons who have undergone surgery or have been injured is a more malignant disease. Large areas of skin are often involved, rapidly prostration is great and death is a common event. In this form of the disorder it is often possible to observe the characteristic recovery of the skin first affected while the process advances elsewhere. This sequence of events also occurs in facial erysipelas but is perceived with greater difficulty. Healing of the skin requires one to two weeks after the temperature has returned to normal.

**Diagnosis** The diagnosis of erysipelas should present few difficulties after the skin lesion has become well established but may be impossible in the case in which fever precedes the signs of local infection. Cellulitis of an extremity or about an operative site may resemble erysipelas as may osteomyelitis of the maxillary or frontal bones; accompanying paranasal sinusitis.

The demonstration of large numbers of hemolytic streptococci in the nasopharyngeal flora or in an operative or traumatic wound provides confirmatory evidence in the diagnosis of erysipelas. Leukocytosis is regularly present in this disease.

sensitivity is concerned leaves many questions unanswered. However there is much to suggest that an antigen-antibody reaction involving one or more of the many products of the hemolytic streptococcus may play a role in the pathogenesis of the disease.

It must be emphasized that only a small percentage of persons who suffer from streptococcal sore throat or scarlet fever subsequently develop rheumatic fever. As virtually all known serological types of group A streptococci appear to be capable of inducing rheumatic fever it is suggested that the relatively infrequent occurrence of the disease is dependent upon host factors rather than on differences in the organism. This point of view is supported by the fact that patients known to have had previous attacks of rheumatic fever show a greatly increased incidence of the disease following streptococcal infections.

It is the opinion of some clinicians that attacks of rheumatic fever may occasionally be initiated by stimuli other than a streptococcal infection. This possibility is not well established since most of the reported cases of this type have not been studied with respect to the possible occurrence of recent streptococcal disease. In any event from the practical point of view it can be stated that if such exceptions occur they must be extremely rare.

**Incidence and Epidemiology.** Rheumatic fever is primarily a disease of childhood with a peak incidence between the ages of five and fifteen years but it is by no means limited to this group. The disease is rare in infants and in adult life it becomes progressively less common with advancing age. It seems probable that its predominance in childhood is directly related to the high incidence of streptococcal infections during this period of life. When unusual conditions result in an increase in the attack rate of streptococcal disease in adult populations as has occurred in the case of certain military establishments the incidence of rheumatic fever appears to be comparable with that seen in childhood.

For many reasons there are no reliable figures which give an accurate picture of the general incidence of rheumatic fever. The disease is not reportable in most communities and even if it were the difficulties of diagnosis would seriously affect the accuracy of the data. Special surveys in individual communities have yielded figures for the incidence which vary over a wide range from 0.1 per cent to more than 5 per cent. As a result of recent studies some

what more consistent figures are available for the frequency with which rheumatic fever occurs following streptococcal infections. In a number of epidemics of streptococcal disease in different localities of the United States the incidence of rheumatic fever was approximately 3 per cent. While the attack rate may be appreciably greater or smaller in certain epidemics this figure provides a reasonable index of the risk of rheumatic fever in untreated streptococcal infections. In contrast to these findings the incidence of recurrences of the disease in known rheumatic subjects has been reported to be as high as 30 to 50 per cent following streptococcal infection.

Despite the inadequacy of statistical information it is generally believed that the incidence of rheumatic fever like that of streptococcal sore throat and scarlet fever has been decreasing for several years. It is possible that the rate of decrease has recently been accelerated by the wide use of antimicrobial drugs. However rheumatic fever remains one of the most important of the serious diseases of childhood.

It is evident from the close relationship between the two diseases that the epidemiology of rheumatic fever may be considered as a special branch of the epidemiology of streptococcal infections. The parallelism between the two diseases is illustrated by the geographical and seasonal variations in their occurrence. In the United States both have their peak incidence during the late winter and early spring and they are encountered with considerably greater frequency in the northern than in the southern states. In individual epidemics the peak incidence of streptococcal disease precedes that of rheumatic fever by one to three weeks as would be expected on the basis of the time interval separating them in individual cases of rheumatic fever.

Rheumatic fever appears to be more common among families in the lower economic group. The effect of poverty is probably dependent upon such factors as malnutrition, overcrowding and substandard housing which in turn lead to an increased incidence of streptococcal disease. There is in addition evidence for an hereditary predisposition to the disease and it is common to obtain a family history of rheumatic fever as well as to encounter multiple cases among the siblings of a single family. It has not been shown that this hereditary predisposition is associated with an increased susceptibility to streptococcal infection.

**Morbid Anatomy.** Histological examina-

## Hemolytic Streptococcal Pneumonia

Group A hemolytic streptococci were once responsible for 3 to 5 per cent of cases of bacterial pneumonia but this form of the disease is now rarely seen. It usually appears as a complication of influenza or other viral respiratory infection or in persons with underlying pulmonary disease. It is almost never observed as a sequel to streptococcal tonsillitis and pharyngitis or scarlet fever.

The pneumonic process is lobular in distribution in the lung. Empyema develops in 30 to 40 per cent of untreated cases. It is present early in the illness and is characterized by the formation of large amounts of thin fluid. Ten to 15 per cent of all cases are bacteremic.

The demonstration of large numbers of hemolytic streptococci in the sputum by cultural methods or the isolation of these organisms from the blood or pleural fluid is required for diagnosis.

Little information is available as to the results of the treatment of hemolytic streptococcal pneumonia with antimicrobial agents. The regimen employed should be that for severe streptococcal infections (see Introduction) and the results should be good with a reduction in mortality from the 15 per cent rate attained with sulfonamides.

It has been demonstrated in a few cases that purulent contents of the empyema cavity may be readily sterilized by the combined intrapleural and parenteral administration of penicillin. In spite of this fluid may continue to form and a long period of time may be required for it to disappear even with frequent aspirations. Recovery is usually facilitated by the closed insertion of a small tube permitting free drainage of the pleural space.

Pneumonia is certainly caused by other streptococci including those nonhemolytic varieties normally present in the upper respiratory tract. The latter may be aspirated and may thus produce disease especially in persons with underlying structural abnormalities of the lung. This type of illness has been little studied and is difficult to recognize clinically.

LOWELL A RANTZ

## Rheumatic Fever

**Definition.** Rheumatic fever is a febrile disease which occurs as a delayed sequel of infections with group A hemolytic streptococci. It is characterized by the occurrence of multiple focal inflammatory lesions in many parts of the body notably in the heart blood vessels and joints. Among the diverse manifestations of the disease those with the most serious clinical implications are concerned with involvement of the heart. Thus the name rheumatic fever which emphasizes the occurrence of inflammation of the joints fails to convey anything with regard to the manifestations of primary importance.

**Etiology.** In recent decades it has become increasingly clear as the result of several independent lines of evidence that group A hemolytic streptococci are intimately concerned in the pathogenesis of rheumatic fever. Numerous clinical and epidemiological studies pointed to a relationship between streptococcal sore throat and rheumatic fever. These observations have been strongly supported by an increasing body of immunological data which demonstrate the occurrence of antibodies to streptococcal antigens in the course of rheumatic fever. Indirect confirmation is provided by the fact that the disease can be prevented by the antimicrobial therapy or prophylaxis of streptococcal infections.

While the importance of streptococcal infections in rheumatic fever appears to be established the mechanism by which the hemolytic streptococci initiate the disease process remains obscure. The disease is not comparable to those bacterial infections in which the organism is readily demonstrable in the lesions. The symptoms of rheumatic fever first become manifest after an interval of several days to several weeks following the acute streptococcal infection at a time when hemolytic streptococci may no longer be recoverable on culture of the nose and throat. Even when streptococci are still present at the time of onset of rheumatic fever elimination of the organisms with penicillin appears to have no striking influence on the manifestations or the course of the illness. It is concluded therefore that the organism exerts its effect through some indirect process rather than by the continued presence of viable streptococci in the tissues of the host. No completely satisfactory hypothesis has been advanced regarding the mechanism of this process and the current theory that some form of hyper

### References

Hemolytic Streptococcal Pneumonia and Empyema. A Study of 55 Cases with Special Reference to Treatment. *Ann Int Med* 14 1933 1941

organ but appears to involve the mesenchymatous connective tissue so that numerous areas of the body may be affected. The major symptoms include fever, pain arising from inflammation of the joints, various manifestations of involvement of the heart and pericardium, abdominal pain, skin changes and chorea. The general symptoms of anorexia, loss of weight, weakness and fatigability are almost invariably present.

The onset of the disease may be insidious and gradual or acute. The relationship to a preceding streptococcal infection is not always clear since the infection can be so mild as to escape notice completely. During the interval between the streptococcal infection and the onset of rheumatic fever, usually a period of one to four weeks, the patient may appear to be entirely well and be able to engage in his normal activity. On some occasions, however, laboratory examinations will reveal evidence of disease activity during this so-called latent interval.

The most common type of onset of rheumatic fever is characterized by the sudden occurrence of fever and joint pain. While the fever may be high and sustained in severe cases, it is more frequently moderate and often low grade. The patient may complain of sore throat, even though examination reveals minimal evidence of acute inflammation and significant bacterial infection may not be demonstrable. Epistaxis occurs commonly both at the onset and throughout the acute stage of the disease and in some cases results in serious loss of blood.

**Joint Involvement.** The manifestations of polyarthritis vary from vague discomfort in the extremities to the exquisite pain associated with acutely inflamed and swollen joints. In the former instance there is little or no objective evidence to confirm the presence of inflammation of the articular surfaces. On the other hand, in the case of the severely involved joint, the skin shows local redness and heat, the joint is markedly swollen with obliteration of the normal configuration and fluid is obviously present within the joint cavity. Passive or active movement of the joint is extremely painful. The fluid in joints of this type is turbid and contains inflammatory leukocytes but is sterile on bacteriologic culture. A single joint may be affected or most of the large joints in the body may be involved at one time. Characteristically, however, the arthritis is migratory in nature and as the pain and swelling subside in one area, others become involved. The

large joints of the extremities are most frequently affected but no area appears to be immune and one may find arthritis of the hands, feet, spine or of such joints as the sternoclavicular and temporomandibular.

There appears to be some variation with age in the pattern of joint involvement most frequently encountered. In the youngest age group in which rheumatic fever is regularly recognized, from four to six years, frank arthritis is a less common feature of the disease. These small children may complain of mild joint pains or merely vaguely localized aching of the extremities. This type of complaint at one time is counted as "growing pains" is usually associated with only low grade fever but despite the benign character of the overt symptomatology can be associated with serious involvement of the heart. Rheumatic fever in older children and young adults is more often associated with the classic migratory polyarthritis, although even in this group the manifestations are diverse. It should be emphasized that rheumatic fever can occur without any evidence of joint involvement whatever.

**Cardiac Involvement.** In the course of acute rheumatic fever, the patient may have little in the way of symptoms referable to cardiac involvement and it is usually necessary to depend on clinical, roentgenographic and electrocardiographic examinations to determine the extent and seriousness of this manifestation of the disease. Since all of the major anatomical divisions of the heart are subject to the disease, the manifestations vary depending on the relative concentration of lesions in the different areas of the heart. Myocarditis and pericarditis are responsible for most of the abnormal findings during the acute stage of the disease and the presence of endocarditis is not readily demonstrated even in those cases in which the subsequent course of events makes it obvious that endocarditis was extensive. Endocarditis involving the leaflets of the valves is responsible for the scarring and distortion which lead to permanent valvular heart disease.

Precordial pain or discomfort is one symptom which is often encountered and it is usually a reflection of myocardial disease rather than of pericarditis. The patient may also complain of palpitation or unpleasant consciousness of the rapid action of the heart. If the disease is sufficiently extensive to cause serious impairment of the function of the heart, the usual symp-

tion of the tissues in rheumatic fever reveals multiple areas of focal inflammation which are disseminated widely throughout the body with special predilection for connective tissue. The basis for the focal nature of the lesions is not determined although it is known that the small blood vessels are extensively involved. The detailed microscopic appearance of the inflammatory lesion varies with its location and the most characteristic and specific pattern is found in the myocardial Aschoff body. This lesion when present in its classic form is generally considered to be pathognomonic of rheumatic fever. In many areas the inflammatory lesion is accompanied by an alteration in the staining properties of the ground substance of the connective tissue. This change is described as "fibrinoid degeneration of collagen" but its chemical basis has not been established. Valvulitis which leads to the most serious permanent damage is characterized during the acute stage by interstitial inflammation and the appearance of minute vegetations on the surface of the valve near its margin.

**Pathological Physiology and Chemistry.** In many respects the alterations in chemical constitution of the body which occur in the course of rheumatic fever are similar to those encountered in other acute febrile diseases. This is particularly true of the numerous changes in the peripheral blood. It has been demonstrated by chemical and electrophoretic analysis that increases in concentration occur in several of the protein fractions of the blood including fibrinogen and alpha and gamma globulins. These increases in protein concentration are accompanied by a variety of changes in the properties of the blood which are dependent upon an increased concentration of certain individual components. Thus the erythrocyte sedimentation rate is markedly elevated and abnormally high concentrations of such constituents as complement, mucoprotein and nonspecific hyaluronidase inhibitor are found. In addition new substances appear which are not normally present in blood. These latter are exemplified by the so-called C-reactive protein and by substances which are bactericidal for a variety of microorganisms.

It should be emphasized that these changes in constituents of the blood are not limited to rheumatic fever but are found in numerous disease states. Some what more specific alterations occur as the result of the appearance of antibodies directed against various components of the hemolytic streptococcus. These antibodies

are responsible for at least part of the observed increase in gamma globulin concentration. They have been demonstrated for several extracellular products of the streptococcal cell such as streptolysin O, streptokinase, streptococcal hyaluronidase and desoxyribonuclease as well as for cellular components such as the type-specific M protein. The anti-streptococcal antibodies usually become detectable in the blood about one week after a streptococcal infection and increase in titer for three or four weeks. Because of the time relationship between precursory streptococcal infection and rheumatic fever the antibody titers are generally still increasing at the time of appearance of rheumatic symptoms. The level of circulating body declines gradually after the peak has been reached.

Numerous comparisons have been made in recent years between the antibody response shown by patients with uncomplicated streptococcal infections and those who develop rheumatic fever as a late complication. It has been found that while there is no consistent qualitative difference between the two groups the proportion of rheumatic patients who develop significant antibody responses to a given antigen is higher than that of patients with uncomplicated streptococcal disease. In individual epidemics of streptococcal infection the mean antibody response of those who develop rheumatic fever is consistently greater than the mean response of the great majority who suffer no complications. The significance of this immunological hyperreactivity of the rheumatic subject in relation to the pathogenesis of the disease has not been established.

Gross changes in the respiratory and cardiac physiology during acute rheumatic fever are dependent to a large extent on the degree of involvement of the heart. When myocarditis is extensive cardiac failure may intervene early in the disease and the alterations dependent on the acute febrile nature of rheumatic fever are complicated by those arising from cardiac decompensation. More subtle disturbances in cardiac physiology frequently result from interference with the conduction system so that alterations in rhythm and various types of heart block are encountered.

**Symptoms and Signs.** The symptoms of rheumatic fever are diverse and cover an extremely wide range both with respect to the variety of manifestations and the degree of intensity with which they occur. In part this is a reflection of the fact that it is not a disease of a single circumscribed

*Pleurisy* which at one time occurred quite frequently in rheumatic fever appears to be an unusual manifestation of the disease at the present time

*Abdominal pain* unassociated with arthralgia or arthritis may be the presenting complaint at the time of onset of the disease. This symptom is most commonly encountered in children and although the pain and associated tenderness are usually not well localized their significance is frequently misinterpreted. In some instances bouts of abdominal discomfort or pain persist throughout the period of activity of the disease. The precise origin of these abdominal symptoms has not been established.

The characteristic manifestation of *skin involvement* in acute rheumatic fever occurring in about one fourth of childhood cases is a multiform type of erythema commonly designated as *erythema marginatum* or *circinatum*. It consists of roughly circular lesions which may be distributed over the extremities, trunk and sometimes the face and which spread centrifugally leaving a clear center. The lesions tend to coalesce so that although individual areas are iris like the larger areas are serpiginous in outline. The erythema blanches on pressure and may be quite evanescent disappearing and later reappearing at the same sites. The lesions are usually not elevated although in some cases a slight papular quality may be detected. In the vast majority of instances the rash occasions no discomfort but well authenticated cases have occurred in which itching has been a troublesome factor. *Erythema marginatum* is not pathognomonic of rheumatic fever and similar rashes may occur in association with other diseases. Rarely purpura is seen in rheumatic fever.

*Erythema nodosum* is another skin disorder which appears to be a manifestation of the acute rheumatic process. However it is not nearly so frequent in occurrence as erythema marginatum and often occurs when other evidence of rheumatic disease is equivocal or lacking. It would appear that only a portion of the cases of erythema nodosum are referable to rheumatic fever. The dull red nodular lesions occur most frequently on the extensor surfaces of the extremities and vary in size from less than one centimeter to many centimeters in diameter. They are extremely tender on pressure and the pain is aggravated by movement of the extremities.

*Subcutaneous rheumatic nodules* represent a quite different type of lesion. These

are firm insensitive nodules which occur over the bony prominences of the various joints and tendons of the extremities, the spine and the back of the head. They appear to be loosely attached to the underlying tissue and the skin is freely movable over them. Increasing the tension of the skin by flexion of the joints makes the nodules more readily apparent and it is often necessary to use this procedure in order to detect the presence of small nodules. When nodules are numerous there is a tendency for them to be symmetrical in distribution. Subcutaneous nodules are most frequently encountered in the more severe cases of rheumatic fever with serious cardiac involvement. In part this may be due to the fact that the presence of nodules is much more readily detectable when there is loss of subcutaneous tissue as the result of chronic rheumatic disease. Thus patients with nodules usually also show marked evidence of wasting and loss of weight.

*Chorea* may occur as a manifestation of rheumatic fever either alone or in combination with other symptoms of the disease. While there is some question whether all cases of pure chorea without other evidence of rheumatic disease are related to rheumatic fever there is no doubt that it occurs as the sole manifestation of the disease in some cases. When chorea is unassociated with other rheumatic symptoms, fever and other systemic changes reflected by such tests as the erythrocyte sedimentation rate are usually absent. It would appear that when rheumatic involvement is confined to the central nervous system the characteristic general systemic response is reduced to a minimum.

The onset of chorea is usually insidious and the parents of a child with chorea may first note only increased awkwardness and a tendency to spill food or drop objects which is attributed to carelessness. Even the appearance of involuntary purposeless movements of the extremities may be discounted as nervousness. However with further progression of the disease the irregular and uncontrollable movements become obvious. These may be extensive and involve not only the hands, feet, arms and legs but the tongue and facial muscles. The severity may range from cases in which the movements are detectable only after close observation to those in which violent continual activity totally incapacitates the patient and necessitates protection from self injury. In moderate cases it is common for chorea to interfere with

toms of cardiac failure will be superimposed on those of the acute rheumatic process

The findings on physical examination reflect the same wide variation in severity of disease that the symptoms display. In the simple relatively benign case there may be nothing more than a tachycardia which cannot be interpreted as unequivocal evidence of cardiac involvement. In the more severe cases one may detect generalized cardiac enlargement and in addition to the rapid heart rate the heart sounds in the apical area may be muffled, indistinct and of poor muscular quality. The latter findings are often associated with a diffuse precordial impulse. The second sound in the pulmonic area is commonly greatly accentuated in comparison with the second aortic sound. Gallop rhythm may occur and is usually an indication of serious myocardial disease.

The cardiac murmurs which appear during the acute phase of initial attacks of rheumatic fever are most frequently blowing systolic murmurs best heard in the apical area and are considered to be caused by dilatation of the valve rings as a result of general dilatation of the heart. Less commonly soft diastolic murmurs will be heard along the left sternal border in the third and fourth interspaces. It is difficult to determine whether inflammation of the valve leaflets contributes significantly to these murmurs. As the murmurs may disappear permanently on recovery their final significance cannot be determined except by repeated examination during and after convalescence.

When the pericardial component of carditis becomes extensive the classic to and fro friction rub will be heard over the precordium. This physical sign may be of brief duration or may persist for days and it will sometimes disappear with the accumulation of fluid in the pericardial sac.

*Disturbances in the conduction system* of the heart are best detected by the use of electrocardiography. Occasionally however irregularities in the rhythm resulting from second degree heart block can be recognized clinically. The most common manifestation of interference with conduction in rheumatic fever is prolongation of the P-R interval in the electrocardiogram reflecting a delay in transmission of the excitation wave from auricle to ventricle. The interference with conduction may be increased to the point where dropped beats result and the rhythm may assume a regular pattern with the beats occurring in

couplets or triplets. Complete auriculo-ventricular dissociation may also occur with the ventricles assuming a rhythm independent of that of the auricles. More rarely auricular fibrillation will make its first appearance during acute rheumatic fever. In addition to these conduction anomalies the electrocardiogram may show T wave abnormalities most commonly in version of the wave in one or more leads. In the presence of pericarditis elevation of the S-T segment may occur in the acute phase with subsequent alterations in the configuration of the T wave which simulate those seen in coronary disease.

The roentgenographic findings may be unremarkable in acute rheumatic fever unless the myocarditis is sufficiently severe to give rise to dilatation of the chambers of the heart. When dilatation occurs generalized enlargement of the heart is apparent on roentgenography and changes in size may occur quite rapidly as a result of changes in the activity of the disease process.

The foregoing description of the findings referable to cardiac involvement is applicable to those cases of acute rheumatic fever in which previous damage to the heart has not occurred. However since rheumatic fever is characteristically a recurrent disease it is common to encounter the acute disease in patients with well-established rheumatic valvular disease. This may occur even in the absence of a history of previous attacks of rheumatic fever. In cases of this type the manifestations of acute rheumatic carditis are superimposed on those of chronic valvular disease. The character of established murmurs may be modified by the acute myocardial disease and the reserve of the heart is diminished so that cardiac failure is a greater threat. If the status of the patient prior to the onset of the acute attack is unknown it is frequently difficult to distinguish between the effects of the acute process and those of chronic disease until convalescence is complete.

*Miscellaneous Clinical Manifestations*  
Involvement of the lung in rheumatic fever leads to a type of pneumonitis which is very difficult to detect clinically. The existence of rheumatic pneumonia was first established by the pathological examination of postmortem material. It is most common in the severe and fulminating cases in which any clinical or roentgenographic evidence of a pneumonic process may be obscured by acute congestion of the lungs resulting from cardiac failure.

result does not eliminate the possibility of a recent streptococcal infection. Secondly patients with nonrheumatic disease may also show evidence of an antibody response to a streptococcal infection which is unrelated to their presenting illness particularly during periods of high incidence of streptococcal disease. Despite these limitations the antibody tests are valuable additions to the total collection of facts which must be evaluated in reaching a diagnosis.

Among these tests the most widely employed and the most practical for general use is the measurement of antibody against streptolysin O. The antistreptolysin O titer is significantly elevated (above 150 units per ml) in 85 per cent or more of rheumatic fever patients. The significance of the antibody information can be increased by carrying out determinations of more than one antibody and in some cases it is helpful if facilities are available to measure antistreptokinase and antihyaluronidase in addition to antistreptolysin O. The absence of a significant elevation in titer of any of the three antibodies would render the diagnosis of rheumatic fever doubtful.

Other laboratory tests used in rheumatic fever such as the erythrocyte sedimentation rate offer relatively little assistance in diagnosis and are of value chiefly in following the activity of the disease process once the diagnosis has been established.

**Differential Diagnosis.** Because of the protean manifestations of rheumatic fever a wide variety of clinical conditions must be considered in differential diagnosis. Low grade febrile illnesses of undetermined origin frequently present the most difficult diagnostic problems. The possibility that illnesses of this type represent subclinical or smoldering rheumatic activity must be considered and this is especially true when the common symptom of pain or discomfort in the extremities is present. The problem becomes even more pressing when low grade febrile disease occurs in a person known to have previously suffered one or more attacks of rheumatic fever. In this instance the marked tendency of rheumatic fever to recur increases the likelihood that the obscure disorder represents rheumatic activity. The problem can be resolved only by close observation and careful study to uncover additional evidence for or against the diagnosis. Chronic upper respiratory disease, chronic tonsillitis, brucellosis and infectious mononucleosis are among the diseases which must be considered in this connection.

Intercurrent respiratory disease or other

febrile illness in children with previously undiagnosed congenital heart disease may be confused with rheumatic fever if cardiac murmurs arising from the congenital defect are misinterpreted as rheumatic in origin. Thorough study of the cardiac abnormality will usually reveal its nature.

**Acute septic arthritis.** For example streptococcal or gonococcal arthritis will simulate rheumatic arthritis especially in the early stages when the inflammation of the joint is indistinguishable from that seen in the severely involved joint in rheumatic fever. As the disease progresses the manifestations of the septic joint are more severe than observed in rheumatic fever and there is a marked tendency for inflammation and edema to extend into the soft tissues at some distance from the joint. The diagnosis can be readily established by removal of fluid from the involved joint for bacteriological examination. Among other acute bacterial infections, acute staphylococcal bacteremia may also simulate rheumatic fever in its early stages since wide dissemination of the organisms may lead to transient symptoms of multiple joint involvement as well as to pleurisy and pericarditis. In addition before the pain of staphylococcal osteomyelitis becomes sharply localized this disease may be confused with rheumatic fever. When joint involvement occurs in serum disease the clinical picture is similar to that of certain cases of rheumatic fever.

**Chronic rheumatoid arthritis.** Especially in the early months of the disease before the chronicity of the process and the extensive nature of the articular damage become apparent must be distinguished from rheumatic fever. Although cardiac signs and symptoms and other stigmata of rheumatic fever are usually absent continued observation for many weeks is sometimes required before the diagnosis can be eliminated as a possibility. Similarly the arthritis due to gout must be considered in the differential diagnosis in the adult. Among rare disease states certain cases of periarthritis nodosa and disseminated lupus erythematosus may be difficult to differentiate from rheumatic fever in early stages of the disease.

**Subacute bacterial endocarditis.** occurs most commonly in persons with valves previously damaged by rheumatic fever and it often presents a clinical picture which is not readily distinguishable from a rheumatic recurrence. Vague pains in the extremities are more common than overt arthritis but these symptoms together

all coordinated operations such as writing and eating. In some cases chorea may be limited to one side of the body. The disease appears to affect females somewhat more frequently than males, although this sex preponderance probably has been overstressed in the past.

**Laboratory Findings:** *Hematology.* Alterations in the leukocytes during acute rheumatic fever are similar to those encountered in an acute streptococcal infection. A definite leukocytosis is usually encountered with total leukocyte counts ranging from 12 000 to 24 000 per cu. mm. This is associated with an increase in the percentage of polymorphonuclear elements.

A moderate degree of anemia is found in the majority of cases. This anemia is usually normocytic in type with proportional decreases in the hemoglobin concentration and erythrocyte count. It is similar to the anemia encountered in infections and to some extent may have its origin in the precursory streptococcal infection. However, the anemia does not tend to improve while the rheumatic process remains active. In many cases the anemia is superimposed on a pre-existing nutritional anemia and may be more severe in degree. The most severe anemias encountered in rheumatic fever are those associated with loss of blood resulting from epistaxis.

**Urinary Findings.** A high percentage of patients with rheumatic fever show the presence of some proteinuria and an increase in the numbers of formed elements in the urine during the acute phase of the disease. However, the changes are rarely as marked as those characteristically encountered in acute hemorrhagic nephritis and it is uncommon to find the two diseases simultaneously in the same patient despite the fact that both follow infection with hemolytic streptococci.

**Diagnosis.** In the classic case of rheumatic fever diagnosis presents no problems. Thus, when one is confronted with a patient who develops fever, migratory polyarthritis, unequivocal evidence of carditis and erythema marginatum three weeks following a severe sore throat, there is little doubt concerning the correctness of the diagnosis. This type of case is relatively unusual, however, and it is more often necessary to rely on careful evaluation of all available lines of evidence, including history, symptoms, signs, and laboratory data. Criteria for diagnosis of rheumatic fever have been suggested on the basis of the combination of major and minor manifestations of the disease which should be

considered as the minimal requirement but in practice it is not possible to adhere rigidly to any formula for diagnosis. Not only do the symptoms of certain other diseases simulate those of rheumatic fever but the overt manifestations of rheumatic fever may be so atypical or minimal as to mislead the diagnostician. In this connection it is pertinent to note that in routine examination of school populations cases of unequivocal rheumatic heart disease with no history of an attack of acute rheumatic fever are frequently encountered and it must be assumed that the acute disease occurred as an undiagnosed illness. When one considers the mildness or the bizarre character of certain cases of known rheumatic fever, it is not difficult to understand how the disease frequently escapes recognition.

It is important to inquire carefully for family history of rheumatic fever and for past illnesses that may have represented previous attacks of the disease. The history of sore throat in the weeks prior to the onset of the disease may be helpful as an indication of a precursory streptococcal infection. However, it should be noted that a negative history in this regard is inconclusive, since mild or relatively asymptomatic infections may be disregarded or forgotten by the patient. Evaluation of the various symptoms presented by the patient often requires close questioning concerning their exact nature and timing. Arthralgia and vague pain or discomfort in the extremities, especially in the young child, must be given serious consideration as possible manifestations of the disease. In the doubtful case in which objective joint involvement is lacking, physical examination centers on the attempt to determine whether carditis is present. When recurrence of the disease is suspected in a known rheumatic patient, it is necessary to distinguish between the manifestations of acute carditis and those of established valvular disease.

The difficulties involved in recognition of the disease are increased by the fact that there is no specific diagnostic laboratory test. The laboratory procedures that provide the most assistance in diagnosis are those concerned with the measurement of antibodies to streptococcal antigens, but the most that can be expected of these tests is that they will supply evidence of a recent streptococcal infection. The limitations of this type of evidence are twofold. In the first place, all persons do not show significant antibody responses to a single streptococcal antigen, and consequently a negative

attack of the disease and the danger appears to diminish with advancing age. However, there is no age at which the rheumatic subject can be considered free from the threat of recurrence following an infection with hemolytic streptococci.

The predisposition to bacterial endocarditis is another factor which affects the long term prognosis in rheumatic fever. Prior to the introduction of effective antimicrobial therapy, endocarditis was a uniformly fatal disease and second only to congestive heart failure as a cause of death among rheumatic subjects. The present success in curing a high percentage of cases of endocarditis does not completely remove the serious prognostic implications of the disease, however, since the bacterial infection frequently results in further damage to the affected valves before it is eliminated.

As a result of the widespread use of mitral commissurotomy for surgical correction of stenotic mitral valves, biopsy fragments of the auricular appendage have become available for pathological examination. It has been found that Aschoff bodies are present in the auricular tissue of at least 40 per cent of patients coming to operation, even though care has been taken to eliminate all patients with clinical or laboratory evidence of rheumatic activity. This finding again raises the question of whether rheumatic activity continues at a subclinical level for many years in a high percentage of cases. However, at the present time the significance of the Aschoff body is not sufficiently well established to draw final conclusions concerning the persistence of rheumatic activity on the basis of this finding alone.

**Treatment.** During the acute febrile phase of rheumatic fever, general care is like that of other febrile diseases, with emphasis on maintenance of an adequate fluid intake. Conservative management of the disease requires that bed rest be continued as long as evidence of the disease activity persists. Because of the prolonged nature of the disease in many cases, this requirement poses a special problem in the maintenance of the patient's morale. Therapeutic measures will usually eliminate all symptoms of the disease, and consequently it is difficult to reconcile the patient to the necessity of remaining in bed. Planned recreation and occupational therapy, adjusted to the interests and capabilities of the patient, are essential at the same time. It is advisable to attempt education concerning the nature of this disease. Education must be continued into the period of

convalescence, since the concept of the variability of the outcome of rheumatic fever is often poorly grasped and one must guard against both unnecessary anxiety and unfounded complacency. It is possible for a patient without significant residual heart damage to become psychologically crippled by exaggerated fear of the disease, and on the other hand an individual with serious cardiac involvement may discount the dangers and attempt to carry on all the activities of a normal healthy person. In childhood rheumatic fever, education of the parents assumes first importance.

The necessity for prolonged bed rest has been challenged by some clinicians, and it must be admitted that proof of its value has not been established by controlled experiment. However, it has been repeatedly observed that the most unfavorable results in rheumatic fever occur when intermittent or semi-ambulatory care is practiced. It is permissible to modify the regimen by allowing bathroom privileges and exceptions to the rule that bed rest must be continued until all evidence of disease activity is gone. It may occasionally be made when a minor manifestation of the disease persists in the absence of all other symptoms or signs. Thus, it is difficult to justify keeping a patient in bed solely because of the presence of erythema marginatum.

After rheumatic fever is first diagnosed, a course of penicillin should be given to eliminate hemolytic streptococci. This is advisable even if bacteriological examination yields negative throat cultures for streptococci, since the organisms may remain in inaccessible areas. It is preferable to administer the penicillin parenterally, and 300,000 units of procaine penicillin once a day in children and twice a day in adults for seven to ten days represents an effective dose. A single dose of 1,200,000 units of the long-acting benzathine penicillin may also be used. After completion of the therapeutic course of penicillin, it is important to provide continuous protection from reinfection with hemolytic streptococci, both by attempting to prevent exposure and by instituting a program of prophylactic drug treatment according to one of the regimens discussed below.

The symptomatic treatment of rheumatic fever at the present time is generally carried out with salicylates or with one of the hormone products, cortisone, prednisone, or corticotropin. The relative merits of these agents in controlling the various manifestations of the disease are still under investigation, and it is not yet possible to define

with fever and debility in a known rheumatic individual are sufficient to suggest a rheumatic recurrence. The difficulties are increased by the fact that in some cases it is not possible to recover the offending organism in blood culture. The characteristic petechiae and painful septic emboli of endocarditis are helpful in differential diagnosis (See section on Bacterial Endocarditis in Diseases of the Cardiovascular System).

When abdominal pain is the initial symptom in acute rheumatic fever the illness is frequently mistaken for appendicitis and all too frequently an unnecessary appendectomy is performed. The highly localizing signs characteristic of classic appendicitis are not found but because of the fact that appendicitis in children is often atypical the lack of these findings is not conclusive. However if a brief period for observation is allowed in doubtful cases other manifestations of rheumatic fever may become apparent.

The so-called *benign idiopathic pericarditis* which is apparently not rheumatic in origin is indistinguishable in the acute phase from those cases of rheumatic fever in which pericarditis is the major detectable manifestation. The diagnosis of idiopathic pericarditis is dependent primarily on elimination of other possibilities and on the subsequent course of the disease which is characterized by complete recovery without residual damage. Thus the final conclusion is often reached only in retrospect and must remain somewhat uncertain since rheumatic pericarditis with minimal involvement of the myocardium and endocardium could conceivably behave in a similar fashion.

*Acute aleuemic leuemia* may occasionally mimic rheumatic fever closely with fever and extremity pain. The nature of the disease may not be suspected until the failure of therapeutic measures suggests the possibility. Examination of the peripheral blood and the bone marrow will serve to suggest the correct diagnosis. *Sickle cell anemia* represents a second disease of the blood which can simulate rheumatic fever. It is advisable to examine the blood for sickling in all cases of suspected rheumatic fever in members of the Negro race.

When uncertainty concerning the diagnosis exists it is often useful to employ a therapeutic test with salicylates. The rapidity with which the symptoms of rheumatic fever are controlled by these drugs in many cases is in sharp contrast to its lack of

effect in most of the diseases that cause confusion in the diagnosis.

**Prognosis.** The course of rheumatic fever does not follow any single well defined pattern. Some patients who appear quite ill at the onset of the disease become symptom free in a few days and proceed to rapid and complete recovery so that the total duration of the illness is not longer than three to four weeks. In contrast to this type of illness fulminating attacks may be so overwhelming that death occurs early in the acute phase. At the other extreme there are patients who show persisting evidence of rheumatic activity for many months or perhaps years. Any of the various symptoms of the disease may occur during the course of this protracted form of the disease. In some instances the subacute and chronic type of rheumatic fever is characterized by recurring cycles of activity with intervening periods of relative freedom from symptoms. The importance of these characteristics of the disease from the point of view of prognosis lies in the fact that the course which the disease will follow is totally unpredictable and there is nothing in its pattern during the early stages which can be relied upon to indicate the probable duration of the illness or the likelihood of the appearance of permanent cardiac damage.

Death in the acute phase of the first attack is rare but the incidence of fatality increases in recurrences of the disease in which the acute process is superimposed on permanent cardiac damage resulting from previous bouts of rheumatic fever. Cardiac failure appears to be the immediate cause of death in these patients. The clinical impression that the severity of rheumatic fever has tended to decline in recent decades is supported by figures indicating that the fatality rate has decreased.

The long term prognosis is dependent primarily on the nature and degree of cardiac involvement. Extensive malformation of one or more of the valves leading to serious interference with the efficient functioning of the heart greatly decreases the life expectancy of the patient. Follow up studies on large groups of rheumatic patients have shown that the majority of those with severe cardiac involvement as indicated by marked enlargement of the heart or congestive failure succumb within ten years. The prognosis is also affected by the fact that a new attack of rheumatic fever may contribute further damage. Recurrences of the disease are most frequent in the first five years following the initial

Secondly, since the hormones may completely suppress the overt manifestations of bacterial infections it is important to give suitable antimicrobial therapy during long continued hormone administration. Penicillin can be used for this purpose at dosage levels recommended for prophylaxis of streptococcal infections. Theoretically one of the broad spectrum drugs such as the tetracyclines would provide protection against a wider variety of infections but their effectiveness in patients receiving hormone therapy is less well established.

Other drugs such as aminopyrine hydroxyphenylcinchoninic acid and gentisate have been employed for symptomatic control of rheumatic fever but at the present time salicylates and the hormones appear to be the drugs of choice.

When cardiac failure supervenes in the course of acute rheumatic fever the general measures employed for the treatment of congestive failure must be added to those for management of the acute disease. Digitalis should be administered according to the dosage schedule outlined in the chapter on valvular heart disease.

**Duration of Therapy.** The difficult problem of determining how long therapy should be maintained is the same regardless of the agent employed. Since the various changes in the blood revert to normal under suppressive therapy there is no laboratory test which serves as a reliable guide to the persistence of the active rheumatic process. The best that can be done once the general improvement of the patient suggests that recovery may have occurred is to withdraw the therapeutic agent gradually and to observe carefully for the return of symptoms or signs of rheumatic fever. If unmistakable signs of severe activity reappear there is no alternative but to reinstitute therapy. In this connection it is important to differentiate between a true recrudescence of rheumatic activity and the so-called *rebound phenomenon*. The latter phenomenon occurs to some degree in a high percentage of patients upon withdrawal of therapy and is a self limited episode characterized by the return of certain manifestations of the disease. Thus there may be a change in the laboratory tests specifically some elevation in the sedimentation rate and reappearance of C reactive protein in the blood and on some occasions symptoms such as low grade fever or arthralgia may occur. Since these mild

manifestations disappear spontaneously in one to three weeks it is unnecessary to resume therapy. However when unmistakable evidence of carditis recurs it is not advisable to withhold treatment regardless of the mildness of the symptoms.

**Prophylaxis: Prevention of Recurrence in a Rheumatic Subject.** The prevention of recurrences of rheumatic fever depends on the prevention of streptococcal infections and every rheumatic patient should receive continuous prophylactic therapy through the school age and for at least five years following the last attack of the disease. Because streptococcal infections can occur at any age prophylaxis should probably be continued indefinitely in all patients with significant heart disease. The most practicable regimens involve the use of sulfadiazine or oral penicillin. The dose of sulfadiazine is 0.5 gm for children under 60 pounds and 1.0 gm for older children and adults given once daily. Because of the more rapid elimination of penicillin it is advisable to give this drug twice daily in doses of 100,000 to 200,000 units. Oral penicillin should be given on an empty stomach preferably before breakfast and at bedtime. An alternative method of prophylaxis is the intramuscular injection of 1,200,000 units of benzathine penicillin every four weeks. This is especially useful whenever the self administration of oral drug is irregular or unreliable.

**Prevention of Rheumatic Fever in a Non-rheumatic Subject.** In addition to this prophylactic effect of antimicrobial drugs it has been shown that prompt and intensive penicillin treatment of established streptococcal infections greatly reduces the risk of the subsequent development of rheumatic fever (see Introduction to Streptococcal Infections). This fact stresses the importance of accurate and early diagnosis of streptococcal disease in all patients regardless of whether there is previous history of rheumatic fever.

an order of preference. The opinion is widely held that the hormones are able to bring about more rapid control of the symptoms especially the manifestation of carditis but it is clear that patients vary in their response to the several drugs so that even this generalization has its limitations. An important practical consideration in therapy is that both salicylates and the hormones suppress the overt manifestations of rheumatic fever without eliminating the underlying disease process. Thus they can not be considered as therapeutic agents in the same sense that an antimicrobial drug is a therapeutic agent in bacterial infections.

When the antirheumatic drugs are given in adequate dosage not only do the signs and symptoms of the disease tend to disappear but the changes in the blood responsible for the various tests for rheumatic activity such as the erythrocyte sedimentation rate revert to normal. Under full treatment therefore the patient may appear to have recovered completely. However upon withdrawal of therapy all the symptoms and abnormalities may rapidly reappear with an intensity as great as that which existed prior to the initiation of therapy.

The current concept of the action of these drugs is that they interfere with the tissue reaction to the abnormal process but do little to accelerate its elimination from the body. They serve the purpose therefore of reducing the inflammatory response and maintaining the patient in a state of relative well being while the body gradually disposes of the substances responsible for the disease.

Salicylates may be given in the form of acetylsalicylic acid or sodium salicylate in a total daily dose of 0.064 gm (1 grain) per pound of body weight (0.15 gm per kg) varying from 3 gm in young children to 10 gm or more in adults given in equally divided doses at four hour intervals. Individual variation in the efficiency of absorption or excretion of the drug and in its therapeutic effectiveness requires readjustment of the dose in many cases. The aim is to give the minimum dose that results in full control of symptoms and to avoid serious toxic side reactions. Studies on the concentration of salicylates in the blood have shown that it is usually necessary to attain a level of at least 25 mg per 100 ml to obtain full effect and that this concentration is sometimes reached with less than 0.064 mg per pound while at other times more is required.

The most common toxic manifestations of salicylate therapy are nausea vomiting and gastric distress. Tinnitus and some degree of temporary impairment of hearing usually occur at full therapeutic dosage. Hyperventilation is commonly seen but the severe acidosis characteristic of intoxication with methyl salicylate rarely occurs in the course of treatment of rheumatic fever. Occasionally mental disorientation and delirium may be seen as a manifestation of salicylate toxicity. In practice nausea and vomiting are the most frequent causes of difficulty in maintaining an adequate dose of the drug. Although this toxic effect is not due solely to local action on the gastric mucosa it is sometimes beneficial to use enteric coated drug. In addition better tolerance of the drug is established if the initial dosage is somewhat below the optimum and gradually increased over a period of a few days. The use of sodium bicarbonate is contraindicated because it reduces the efficiency of absorption of salicylate.

**Hormonal Therapy.** Ideal dosage schedules for the use of the hormone products in rheumatic fever have not yet been determined. The most generally accepted procedure at the present time is to begin with relatively large doses until the activity of the disease appears to be under control and then to reduce the dosage to the minimum amount which will maintain full effect. The initial dose of corticotropin is 10 to 20 mg per pound per day given intramuscularly in four equal doses at six hour intervals. The use of cortisone or prednisone offers the advantage of oral administration. The initial dose of cortisone is 2 to 4 mg per pound per day in divided doses and that of prednisone one fourth this amount. The full effect is usually obtained within one or two days and the dose can then be adjusted to the smallest amount that will suppress all symptoms and signs of the disease. This serves to minimize the side effects associated with hyperadrenism. The possibility that continued administration of large doses may reduce the incidence of permanent heart damage is still under investigation.

In two separate areas auxiliary therapy is required to counteract certain effects of the adrenal hormones unrelated to control of the rheumatic process. Because of the effect of the hormones on the salt and water balance of the body a low sodium diet should be provided. This is of particular importance in the presence of extensive carditis when accumulation of fluid may increase the risk of cardiac failure.

tated patient and the newborn infant appear to be especially susceptible to infections. Presumably staphylococcal infections arise from carriers and from environmental contamination but the relative importance of these two sources of organisms is unknown.

**Treatment.** Certain general principles should be followed in the treatment of all staphylococcal infections. Of primary importance is the surgical drainage of abscesses since the available antistaphylococcal drugs are markedly reduced in effectiveness in the presence of pus. Before the days of antimicrobial therapy patients with bacteremia were occasionally cured by the drainage of an abscess.

In general the drugs useful in the treatment of staphylococcal infections include penicillin, erythromycin, novobiocin, bacitracin, the tetracyclines, chloramphenicol, and streptomycin. Treatment must be prolonged since the organisms are killed slowly. This is in striking contrast to the rapid bactericidal action of certain of these drugs, notably penicillin on pneumococci or group A streptococci. It is difficult if not impossible to recommend a single therapeutic regimen for all staphylococcal infections because the susceptibility of the various strains of staphylococci to each antimicrobial drug appears to be changing rapidly. Indeed the drug of choice in certain geographical areas may be relatively ineffective in others. Infections acquired in the general population are frequently susceptible to penicillin, whereas staphylococcal disease contracted in the hospital may be resistant to therapy with penicillin or with the other antimicrobial drugs commonly employed in that clinic. The nature and location of the infection also alter the method of treatment. Sufficient data are not available to allow critical evaluation of the use of combinations of antimicrobial drugs in the treatment of staphylococcal infections.

Drug susceptibility tests of the infecting strain of staphylococcus are invaluable in guidance of therapy. In areas where such tests cannot be obtained, penicillin, streptomycin, with penicillin or erythromycin should be administered in full dosage and if a favorable response is not observed after a few days therapy should be altered. In severe infections initial therapy should include penicillin or erythromycin in combination with either streptomycin or bacitracin. The latter drug should be given in doses of 15 000 to 20 000 units four times daily and should not be employed if there

are signs of renal failure. The choice of drug or combination of drugs after the first few days of treatment should be governed by the results of the drug susceptibility studies of the strain of staphylococcus involved.

Within the hospital every effort should be made to prevent the spread of staphylococcal infections. The patient exhibiting such an infection should be isolated for protection of personnel and other patients. The indiscriminate use of antimicrobial drugs should be avoided since drug-resistant strains are maintained in the hospital by such practices. In the larger hospital it is advisable to withdraw one antimicrobial drug from general use so that when serious staphylococcal infections arise the drug may be used to combat them.

## Furuncles and Carbuncles

**Definition.** A *furuncle* or boil is a circumscribed suppurative inflammatory lesion of the skin and the immediate subcutaneous tissues. A *carbuncle* which may be considered a furuncle with multiple foci develops when a suppurative infection occurs in thick inelastic skin and extends into the deeper layers of fibrous tissue.

**Etiology.** Furuncles and carbuncles are most commonly caused by *Staphylococcus aureus*.

**Symptoms.** Although furuncles occur in any location they are especially prone to occur on the face, neck, forearms, axillae, midline and upper part of the back, breasts, groins and legs. Carbuncles are essentially limited to the nape of the neck and back.

Careful observation will show that most of these infections begin with a small pustule at the base of a hair follicle. At this stage there is no pain, perhaps only an itching sensation. Within a few hours swelling and redness occur and some pain is experienced. Gradually over a period of three to five days the boil becomes elevated; the involved area is exquisitely tender and movement of the involved part causes pain. At the apex of the swelling the skin glistens and becomes thinned and a yellow spot appears. The boil is now said to be pointing and shortly will drain spontaneously. The pus is creamy yellow in color and at the center of the boil a hard core may be evident.

At the time of rupture of the abscess pain is relieved almost immediately. The abscess continues to drain a serosanguineous

## Staphylococcal Infections

### Introduction

Staphylococci are responsible for most suppurative infections of the skin and not infrequently cause infection of the lungs bones kidneys and other organs Typically such infections are associated with abscess formation

Staphylococci may be divided into three species according to the color of pigment produced Pigment production is best demonstrated in freshly isolated strains grown on solid medium at 22° C *Staphylococcus aureus* is golden yellow *S. albus* is white and *S. citreus* forms a lemon yellow pigment Strains of *S. aureus* are responsible for the majority of infections in man *S. albus* may occasionally cause mild infections *S. citreus* rarely infects man

*Staphylococcus aureus* produces toxic substances with hemolytic necrotizing leukocytolytic and lethal properties A small number of staphylococci produce an enterotoxin which is responsible for most cases of food poisoning In addition they produce an enzyme hyaluronidase or spreading factor which hydrolyzes hyaluronic acid Although antisera to some of these toxic substances have been prepared they have not proved especially useful in the treatment of infections in man

Pathogenic strains of staphylococci may be recognized by several methods Most strains isolated from infections ferment mannite Another characteristic of pathogenic strains is their ability to grow in human whole blood whereas nonpathogenic strains are easily killed in the bactericidal test The ability of certain staphylococci to coagulate plasma has long been recognized and used as a laboratory test for pathogenicity Recently the mechanism of this reaction has been elucidated Staphylococcal coagulase reacts in some way with a factor (reacting factor) present in blood to produce a clotting substance Coagulase is antigenic and after infection an antibody develops which inhibits the coagulase reaction In order to demonstrate such antibodies the specific coagulase produced by the infecting strain must be utilized

**Pathogenesis** Invasion of the tissues by pathogenic staphylococci follows a rather characteristic course The organism multiplies locally and is probably facilitated in its spread by the production of hyaluroni-

dase which increases the permeability of the connective tissues The organism may be protected from the phagocytic cells by the deposition of a thin barrier of fibrin at its periphery through the production of coagulase The organisms multiply locally and produce toxins and more coagulase Presumably coagulase diffuses into the surrounding tissues and accounts for local thrombosis in the blood vessels The toxins meanwhile cause marked inflammatory changes in the tissues and necrosis occurs centrally Eventually the abscess ruptures and repair of the tissue begins Occasionally when the organism is especially virulent the local barriers break down and bacteremia becomes evident Certain animals notably birds do not develop abscesses when pathogenic strains of staphylococci are injected This may be due to the fact that coagulase fails to act on plasma of birds because of an apparent deficiency in the amount of reacting factor in the blood

**Epidemiology** By means of bacteriophage typing the epidemiology of staphylococcal infections has been clarified to some extent It has long been recognized that staphylococci may be cultivated from various parts of the body More than half of the population carry *Staphylococcus aureus* in the nasal secretions and most persons harbor the same organism on the skin Nasal carriers are especially likely to be skin carriers The fact that the bacteriophage types of the organisms isolated from the nose and skin of one person are the same suggests a common source Apparently the skin is being continuously contaminated by the nasal secretions Staphylococci are most frequently found on the backs of the hands over the forearm and back of the neck and somewhat less commonly along the midline of the body and in the inguinal folds

In recent years it has become apparent that the hospital is a major source of serious staphylococcal infections In this environment where many patients are receiving various antimicrobial drugs strains of staphylococci resistant to these drugs are constantly present These strains are likely to be especially virulent They may be isolated from patients and staff as well as from dust blankets clothing and air Furthermore the postoperative or debili-

plication of staphylococcal bacteremia Staphylococcal pneumonia also develops in patients receiving antimicrobial drugs for other infections *Fibrocystic disease of the pancreas* is often complicated by chronic staphylococcal infections of the lung

**Morbid Anatomy** The mucosa of the trachea and bronchi is ulcerated and intensely inflamed and is covered with thick purulent secretions. Around the bronchi the alveoli are filled with an inflammatory exudate containing blood and fibrin. Multiple small abscess pockets are observed some communicating with bronchi. Necrosis of the lung parenchyma is prominent.

**Symptoms** Staphylococcal pneumonia is usually preceded by a respiratory infection the symptoms of which may include sore throat, cough or generalized malaise and fever. After a variable period of one to several days the patient suddenly becomes quite ill. The temperature increases there may be a rigor and the cough becomes aggravated and productive of purulent sputum. At times the sputum may be streaked with blood or is brownish or yellowish in color. Pleuritic pain is common.

In some patients the course of the disease may be rapidly fatal with a sudden onset prostration, a peculiar reddish blue cyanosis, rapid respirations and high fever. In others the disease appears to be more chronic with remittent fever but moderately rapid pulse.

The physical signs in patients with staphylococcal pneumonia are not characteristic but are variable. Early there may be no change in the percussion note. Later dullness to percussion is exhibited. Rales both coarse and fine may be elicited over the involved area of the lung. Since pleural effusion and empyema are common, dullness and other signs of fluid may be found.

The leukocyte count is elevated to between 15,000 and 25,000 per cu mm. rarely it is low or normal. Roentgenograms of the chest show one or more areas of consolidation near the hilum of the lung. Later cavities may develop and their fluid levels can be easily demonstrated in the roentgenogram. Pleural fluid is common.

**Diagnosis** Cyanosis, remittent fever and purulent sputum should lead one to suspect staphylococcal pneumonia. The diagnosis is dependent on the isolation of *S. aureus* in relatively pure culture from the sputum. The development of empyema from the fluid of which staphylococci may be cultured aids in the establishment of the diagnosis. Abscess formation as shown by

the roentgenogram is characteristic. The blood culture which should be made in each case is usually sterile. When bacteremia is present the pneumonia may be secondary to a focus elsewhere in the body.

**Differential Diagnosis** One must consider all other forms of bacterial pneumonia and primary atypical pneumonia in the differential diagnosis. Abscess formation is most apt to occur in staphylococcal, streptococcal and klebsiella (*Friedlander's bacillus*) pneumonia. Pneumonia caused by the *Friedlander bacillus* is confused with staphylococcal pneumonia because of the remittent character of the temperature. Careful culture of the sputum is the only method of establishing the diagnosis.

**Prognosis** Most patients recover from staphylococcal pneumonia but a few succumb. The illness in those who recover usually lasts three or four weeks and recovery is gradual.

**Treatment** As in all severe infections the staphylococcus isolated from the patient should be tested for susceptibility to the various antimicrobial drugs. If the organism is susceptible to penicillin 2,000,000 to 4,000,000 units should be administered in divided doses every four hours. It is also advisable to administer streptomycin. Bacitracin or erythromycin may be substituted for streptomycin if the organism is susceptible to one or another of these drugs. Treatment should be maintained for at least one week after the temperature returns to normal. As in other staphylococcal infections the temperature falls slowly after institution of specific therapy. Empyema should be treated early by the intrapleural injection of 50,000 to 100,000 units of penicillin every twenty-four to forty-eight hours. The intrapleural instillation of the enzymes streptokinase and streptodornase is advisable as discussed in a later section on Empyema. If the intrapleural fluid is thick surgical drainage may be required in addition to penicillin therapy.

The general management of the patient with staphylococcal pneumonia is identical with that described in the section on Pneumococcal Pneumonia (p. 126).

## Osteomyelitis

**Definition** Osteomyelitis is an infection of the bone most frequently caused by *Staphylococcus aureus*.

**Etiology** Staphylococci reach the bone after invasion of the blood stream. The

eous fluid swelling decreases and within a few hours to days the discharge ceases. Redness may persist for several days or weeks but eventually all signs of the abscess disappear.

Although this description applies to the majority of boils, certain features of these infections deserve emphasis. Infections of the hair follicles which never involve the surrounding tissues are known as simple *folliculitis*. They are apt to occur in persons who are in constant contact with oil, grease and other skin irritants. People with prominent sebaceous glands are prone to suffer staphylococcal infection which the dermatologists designate as *pustular acne vulgaris*. These infections are seen over the face and the upper part of the back.

Furuncles occasionally occur in the axilla but most infections in this region arise in the sweat glands, hence the name *hidradenitis*. These infections start as small inflammatory nodules which cause considerable discomfort. When the abscess discharges, the organisms invade other sweat glands and hair follicles with subsequent scarring of the tissues.

A single boil may be followed by multiple infections of the surrounding skin, i.e. *furunculosis*. The secondary infections are due to the purulent discharge from the abscess invading other hair follicles in the adjacent skin. Boils around the nose and lips are especially dangerous since local trauma may result in the invasion of the venous sinuses within the skull.

Characteristically the carbuncle occurs at the nape of the neck and begins with infection of one or usually several hair follicles. As a result, the area of swelling and redness is wide and the surface is covered with multiple pustules. As the infection spreads, the center becomes a grayish yellow crater with ragged edges. Most carbuncles are extremely painful, although occasionally they cause little discomfort. The patient's head is usually held rigidly. Older persons may be critically ill and bacteremia is common.

**Diagnosis.** Simple *folliculitis* is frequently caused by *Staphylococcus albus* and is easily recognized because of the lack of redness and induration around the hair follicle. *Pustular acne vulgaris* is always associated with an oily skin. Most furuncles are not associated with a constitutional reaction, whereas a person with a carbuncle frequently has fever and leukocytosis. Cultures of the boil or carbuncle show coagulase positive *S. aureus*. Since diabetics are subject to carbuncles and boils, the urine

should be examined for sugar in all patients with these infections.

**Treatment.** When a furuncle or carbuncle is observed before there are signs of abscess formation, the daily intramuscular injection of 600,000 units of procaine penicillin and/or the administration of 0.5 gm of erythromycin every six hours may abort the process. Usually treatment must be given for at least one week. In the presence of fever, a blood culture should be obtained and the dose of penicillin increased. The application of hot packs to the infected area may relieve pain and aid in the localization of the infection. In all severe infections, the involved part should be immobilized and the patient kept in bed.

In well-localized abscesses, the cavity should be drained and antimicrobial therapy continued until signs of inflammation have disappeared. Moist dressings should not be applied to the skin after the abscess drains, since moisture tends to macerate the skin and facilitates the implantation of organisms. The skin around draining sinuses should be protected by a thick layer of penicillin or tyrothricin cream.

**Prevention.** The prevention of furuncles or carbuncles is difficult, probably because the skin is being continuously contaminated via the hands with virulent staphylococci from the nasal secretions. The patient should be cautioned not to traumatize the skin and to avoid oils, dirt and other skin irritants and to use mild soaps and cool water when washing. Such procedures decrease the opportunity for invasion of hair follicles and sebaceous or sweat glands. When infections recur frequently, the daily application of tyrothricin cream is recommended. Such advice is especially indicated in diabetic patients, since recurrent boils are common.

## Staphylococcal Pneumonia

**Definition.** Pneumonia caused by *Staphylococcus aureus* is characterized by abscess formation.

**Etiology.** Staphylococcal pneumonia is relatively rare except during periods when there are epidemics of influenza, measles or whooping cough. The exact cause for this relationship is unknown. Both in the primary form and in pneumonia secondary to other respiratory infections, staphylococci probably invade the parenchyma of the lung through the bronchial and bronchiolar walls. Isolated areas of pneumonia with abscess formation are a common com-

and this drug should be given in relatively large amounts. Usually 200 000 to 2 000 000 units are injected intramuscularly every three to four hours. In addition either 0.5 gm of streptomycin or 0.5 gm of erythromycin every six hours is advisable. Every effort should be made to isolate the infecting organism so that therapy may be altered according to the results of drug susceptibility tests. Treatment is continued for a minimum period of three weeks. During the later period of therapy procaine penicillin may be substituted for the sodium salt in dosages of 600 000 units twice daily. Such therapy instituted within four days of onset usually results in the subsidence of signs of inflammation within two to four days and minimal or no damage to the bone can be demonstrated in the roentgenogram. In those patients whose disease has been present for four days or longer localized abscesses may form and damage to the bone is more extensive. Small sequestra usually absorb but larger pieces of dead bone may require removal. In addition to these measures the fluid balance is to be maintained and severe degrees of anemia should be corrected by blood transfusion.

**Chronic Osteomyelitis.** The treatment of chronic osteomyelitis usually requires sequestrectomy saucerization of the infected bone and removal of the sinus tract. The antimicrobial drugs in the amounts already indicated should be administered before and after operation. In a few patients intensive penicillin treatment alone results in eradication of the disease.

## Staphylococcal Bacteremia

**Pathogenesis.** Staphylococci may invade the blood stream from abscesses in any location. The studies of Skinner and Keefer have demonstrated that infections of the skin account for the primary focus in about 40 per cent of the cases. Infections of the bone and respiratory tract account for another 40 per cent and in the remainder the bacteria are fed into the blood stream from the genitourinary tract or from an unknown focus.

Factors which contribute to the frequency of blood stream invasion are trauma and the presence of debilitating disease. Early incision of an abscess or attempts to evacuate the pus by squeezing may result in bacteremia. Such procedures are especially dangerous when the boil is located

about the face. Bacteremia occurs frequently in patients with diabetes, arteriosclerosis, cancer and other debilitating diseases. Operations, especially prostatic resections, are likely to be the source of the bacteremia. Virulent staphylococci are more likely to produce a fatal bacteremia than nonvirulent organisms belonging to the coagulase negative group. Fortunately bacteremia following infections of the skin is rare. In 11 568 patients seen with carbuncles and furuncles Sutherland observed only 7 instances of bacteremia.

**Symptoms.** Typically the patient has chills and fever after invasion of the blood from a boil or carbuncle. The fever may be high and remittent in type or less frequently intermittent. In a few cases the fever is low and continuous. Rigor is observed in about 25 per cent of patients. Marked perspiration is common. Complaints such as headache and malaise are frequent but not characteristic of the disease.

One of the characteristic features of *Staphylococcus aureus* bacteremia is the production of metastatic abscesses, whereas *S. albus* does not produce such lesions. Patients who survive *S. aureus* bacteremia more than a few days get abscesses. The most frequent sites of these metastatic abscesses are the skin, subcutaneous tissues and the lungs.

Infection of the lung is a common complication of staphylococcal bacteremia. For this reason every effort should be made to locate the portal of entry of the staphylococcus in patients with pneumonia and a positive blood culture. It will be recalled that primary staphylococcal pneumonia is not commonly associated with bacteremia.

Superficial abscesses of the skin, joints and muscles account for 30 per cent of the metastatic complications. Petechiae and purpura are occasionally seen. Internal abscesses of the kidneys, brain and spinal cord are not uncommon.

Infection of the pleural, peritoneal and pericardial cavities occurs in less than 10 per cent of cases. Sinus thrombosis and meningitis are rare and usually occur as the result of direct extension of the infection. Endocarditis should be suspected when there are cardiac murmurs which change in character or whenever bacteremia persists in the absence of an obvious extra cardiac focus.

**Diagnosis and Prognosis.** The history of a preceding staphylococcal infection in a patient with intermittent fever should suggest the diagnosis of staphylococcal bac-

usual focus is a wound furuncle or other external infection. The initial acute infection is practically confined to children and is more frequent in boys than in girls. The usual explanation for localization in the bone is the fact that the diaphysis of the child gets its blood supply through terminal capillary loops. The bacteria tend to settle out in this area. The fact that the blood of the young child contains little coagulase reacting factor as compared with that of the adult may possibly account for the initial blood stream invasion in the younger age groups.

**Pathogenesis and Morbid Anatomy.** The staphylococci set up an acute inflammatory reaction with necrosis of the bone. The initial infection occurs at the diaphysis and seldom crosses the epiphysis; instead as the infection progresses the pus emerges to the surface of the bone raising the periosteum. Although purulent material is present at an early stage the bone is not destroyed immediately. As the bone dies sequestra are formed. Repair begins after drainage of the abscess; small sequestra may be absorbed and new bone is laid down by the osteoblasts forming the involucrum. Not infrequently a chronic infection of the bone is established which intermittently results in an acute inflammatory process.

**Symptoms.** Acute osteomyelitis is usually ushered in by fever, chills, pain and in the very young patient by nausea and vomiting. Careful examination may reveal a recently healed wound, pustule or furuncle. Pain over the bone may be the only early sign of localization of the infection. Tapping on the bone may cause pain referred to the involved area. Pain sometimes skips around to various bones before it finally localizes. Muscle spasm around the involved bone is a common and frequently early sign of osteomyelitis. At this stage of the disease roentgenograms of the bone reveal no abnormality.

As the infection progresses redness and swelling occur over the involved bone. The patient splints the limb or affected part for movement causes pain. When the infection is near a joint swelling of the periarticular tissues occurs and effusion into the joint is common. The temperature is likely to be high and the patient critically ill. By ten days to two weeks after the onset the roentgenogram may show some rarefaction of the bone. Subsequently periosteal reaction is exhibited by new bone formation. As the bone dies dead bone or

sequestrum may be observed in the roentgenogram.

**Chronic osteomyelitis** is especially likely to occur if sequestra remain unabsorbed or if adequate drainage is not established. Repeated attacks of acute osteomyelitis with the establishment of chronic draining sinuses characterize this phase of the disease. Amyloidosis is a complication of the prolonged suppurative process.

**Diagnosis.** During the first few days of the disease the history of fever, chills and pain over long bones is enough to suggest the diagnosis of acute osteomyelitis. There is usually a leukocytosis of 20,000 or more cells per cu mm and the blood culture frequently shows *Staphylococcus aureus*. As the disease progresses anemia develops. After ten days the roentgenogram exhibits diagnostic abnormalities such as periosteal new bone formation and sequestra.

Acute osteomyelitis must be differentiated from other bacterial infections and erythema nodosum. Usually the diagnosis is not difficult. A serious error can be made however if a patient with acute osteomyelitis is mistakenly considered to be suffering from acute rheumatic fever. A history of recent furunculosis with or without trauma, the usual monoarticular involvement, the degree of leukocytosis (20,000 or more cells per cu mm), the response to penicillin and in some cases the demonstration of staphylococcemia all serve to establish the presence of acute osteomyelitis. This question of the differences between rheumatic fever and osteomyelitis is also discussed in the section on Rheumatic Fever (p. 155).

**Treatment and Prognosis.** Before the introduction of penicillin the case fatality rate for patients with acute osteomyelitis was about 15 per cent in the absence of bacteremia and 25 to 50 per cent in the presence of bacteremia. If the patients survived the initial infection a chronic infection was usually established and metastatic foci in other bones were common. Today death from acute osteomyelitis is rare and chronic osteomyelitis is uncommon.

**Acute Osteomyelitis.** In order to avoid surgical intervention early treatment of acute osteomyelitis is required. For this reason it is advisable not to wait for bacteriological or roentgenographic confirmation of the diagnosis before starting antimicrobial therapy. The initial attack of osteomyelitis is usually caused by an organism susceptible to the action of penicillin.

enhanced by incubating the cultures in an atmosphere containing 10 to 15 per cent carbon dioxide.

Colonies of *N. gonorrhoeae* are gray and translucent and their recognition is aided by performing the oxidase test. A 1 per cent solution of p-aminodimethylaniline monohydrochloride is poured over the surface of the agar plate and within a few minutes colonies of the gonococcus turn pink then purple. A positive test occurs with all members of the genus *Neisseria* and occasionally with certain other bacteria. With cultures from the genital tract a positive oxidase reaction together with characteristic colonial morphology and the presence of gram negative diplococci constitutes presumptive evidence that the organism is a gonococcus. However, since saprophytic *Neisseria* and other bacteria are known to produce false positive results, particularly in women, confirmatory fermentation reactions with glucose, maltose and sucrose should always be performed. Carbohydrate reactions are also used to differentiate gonococci from meningococci when positive cultures are obtained from blood, cerebrospinal or joint fluid. Meningococci ferment both dextrose and maltose while the gonococcus gives a positive reaction only with dextrose. Differentiation can also be accomplished by agglutination tests.

Since the gonococcus is quickly killed by drying, exudates from the genital tract should be cultured directly on agar plates, or the swab should be placed in a small amount of broth while it is transported to the laboratory. Urine should be centrifuged and the sediment inoculated on the culture plate. With cerebrospinal fluid, blood and synovial fluid, in which the number of organisms may be small and contaminating bacteria are usually not present, the best results are often obtained by culturing the specimens in shallow layers of broth enriched with plasma or ascitic fluid using an increased tension of carbon dioxide.

**Epidemiology and Pathogenesis.** Gonorrhea is world wide in distribution and all races appear to be equally susceptible. There is considerable individual variation in resistance to infection, however, the nature of which is not known. Even when massive numbers of gonococci are instilled directly into the urethral canal, less than half the males so inoculated contract the disease.

Accurate information concerning the incidence of gonorrhea is difficult to obtain, since reporting is poor and penicillin is so easily obtainable that many cases are

treated by persons other than physicians. The evidence available indicates that there probably has been a marked decline in the total number of infections since 1945. The disease is still widespread, however, and is prevalent chiefly among lower income groups. Moreover, the lack of immunity following a gonococcal infection makes it possible for a person to have a number of attacks. Analysis of such "repeaters" indicates that in most instances they are either indifferent or are unable to comprehend the facts of prevention and treatment. Transmission of gonorrhea by asymptomatic carriers also tends to propagate the disease. This problem is aggravated by the difficulty in detecting and in eradicating the carrier state, especially in women.

The resistance of stratified squamous epithelium to infection by the gonococcus explains the lack of lesions on the external genitalia of both sexes and in the vagina. The susceptibility of columnar epithelium permits infection of the urethra, prostate, seminal vesicles, epididymis and glands associated with these structures in the male. In women, infection occurs chiefly in the urethra, Skene's and Bartholin's glands, endocervix and fallopian tubes. Once established, the infection tends to persist for weeks or months in the genital tract unless treatment is given. This tendency toward chronicity was one of the factors chiefly responsible for the spread of the disease before effective chemotherapy became available. Persistence of the infection is associated with tissue destruction and abscess formation, leading to urethral strictures in the male and chronic inflammation and sterility in the female. In a small percentage of cases, the organisms find their way into the blood stream and set up metastatic foci in distant organs such as the joints and endocardium.

Nonvenereal transmission of infection by the gonococcus occurs rarely if at all. In stillation of penicillin or silver compounds into the eyes of newborn babies has virtually eliminated ophthalmia neonatorum, formerly an important cause of blindness. Epidemics of vulvovaginitis in young girls were once thought to be neisserian in nature and to be transmitted by bedclothes and towels. It is now realized, however, that in most instances the gonococcus is not the causative agent and when it is, sexual contact has occurred.

**Symptoms and Signs.** From two days to two weeks following sexual exposure, burning on urination is the first symptom of gonorrhea, usually noted in the male and

**teremia** The finding of multiple peripheral abscesses also suggests such a diagnosis. Most patients exhibit a high leukocyte count and anemia. The diagnosis is established by the isolation of the organism from the blood stream.

Before the introduction of modern chemotherapy the case fatality rate was 80 per cent.

**Treatment** The therapy of staphylococcal bacteremia is still unsatisfactory. Every effort should be made to drain all abscesses promptly and treatment should be guided by drug susceptibility tests. In general combinations of drugs are usually employed. The compounds most frequently used are penicillin, erythromycin and streptomycin. The tetracycline drugs, chloramphenicol, novobiocin and bacitracin are given if the organism is susceptible to their action. Each drug should be given in the maximum dose that can be tolerated. Blood transfusions should be given to patients with anemia.

## Enterocolitis

For many years the surgeon has recognized a serious postoperative complication, enterocolitis, which is characterized by the sudden development of diarrhea, vomiting,

abdominal distention, tachycardia, fever, hypotension and shock. More recently a similar syndrome has been observed in other hospitalized patients, especially those receiving wide spectrum antimicrobial drugs. Most cases are apparently caused by staphylococci, since these organisms may be recovered in large numbers from the feces. Characteristically the staphylococci isolated from the stool produce enterotoxin and are resistant to the antimicrobial drug or drugs being administered to the patient. For further discussion of this subject see Enterocolitis (p. 839).

## Gonococcal Infections

**Definition** Gonorrhea, commonest of the venereal diseases, is the principal infection caused by the gonococcus (*Neisseria gonorrhoeae*). From the primary focus in the genital tract the organism may spread to involve other parts of the body, particularly synovial tissues and serosal surfaces, causing a variety of clinical entities such as arthritis, endocarditis and meningitis. Formerly common and important extra-genital infections with the gonococcus have become rare since the advent of penicillin.

**Etiology and Bacteriology** As seen in smears of purulent exudates the gonococcus is a gram-negative, kidney-shaped diplococcus, often located within the cytoplasm of polymorphonuclear leukocytes. This characteristic appearance was first observed in urethral pus by Neisser in 1897. In cultures, single cells tend to predominate and the flattening of one surface of the oval is often absent.

**Primary cultivation** of the gonococcus is difficult because of its fastidious growth requirements and its susceptibility to toxic substances often present in culture media. Blood is commonly used for enrichment and the deleterious effects of certain amino acids are reduced by heating the medium after the blood is added (chocolate agar). Toxic materials present in agar can be neutralized by the addition of starch or charcoal. Dyes such as Nile blue inhibit the growth of contaminating bacteria but do not affect the growth of the gonococcus. Media are commercially available which take advantage of all the known facts concerning growth requirements so that routine cultural techniques are now quite simple. The results still leave much to be desired, however, since the reproducibility in different laboratories using the same cultural techniques is not greater than 75 per cent. The growth of most strains is

involved. Finally there is a group of patients in whom the onset and clinical course are indistinguishable from that of rheumatoid arthritis. The gonococcal infection may provide a "trigger mechanism" for the initiation of this disease. However, some investigators on careful questioning have elicited histories of previous attacks and believe that the gonococcal infection is usually an incidental occurrence in rheumatoid subjects.

Differentiation of gonococcal arthritis from rheumatoid arthritis and acute rheumatic fever is in many instances very difficult. A clear-cut history of gonorrhea may be unobtainable and it is often impossible to culture gonococci either from the genital tract or the joint fluid. The gonococcal complement fixation test is helpful in some cases, particularly when it is negative initially and then shows a rising antibody titer after several weeks. This test, which requires carefully prepared and standardized reagents, is not performed in the ordinary laboratory but is available through most state laboratories.

Reiter's disease, characterized by urethritis, arthritis, and conjunctivitis, also offers serious diagnostic difficulties, especially since a catarrhal form of conjunctivitis occurs in 10 per cent of patients with gonococcal arthritis.

Penicillin reactions and gout are other disorders which can cause confusion. Since a precise diagnosis is often impossible during the early stages, therapy must be started empirically and the response to salicylates or to penicillin is often helpful in establishing the true cause.

Other complications, such as meningitis, myelitis, liver abscesses, and keratoderma blennorrhagica, are now so rare that they have become medical curiosities.

**Diagnosis.** Gonococcal urethritis is readily diagnosed in both sexes when the typical clinical picture is present and gram-negative intracellular diplococci are seen on smears of the urethral discharge. Symptoms are sometimes mild and transient in the male, however, and endocervicitis may pass unnoticed in the female. Unfortunately, there is no reliable method available, especially in females, for detecting the carrier state. Negative cultures do not provide adequate evidence that a person is unable to transmit the disease. Aside from genital infections, the main problems in diagnosis occur with arthritis and salpingitis; the salient differential features have been covered in the preceding section.

**Treatment and Prognosis.** Penicillin is

the drug of choice for the treatment of gonococcal infections. In gonococcal urethritis, a single intramuscular injection of 600,000 units of procaine penicillin will cure over 95 per cent of cases in both males and females. This dose is also adequate to abort syphilis. Longer acting forms of penicillin, either the aluminum monostearate form of procaine penicillin or the newer benzathine penicillin G, may also be used. Recent studies indicate that a single dose of 1,200,000 units of benzathine penicillin G, which gives measurable drug concentrations in the blood for three to four weeks, is effective, particularly in women, both in eradication of the carrier state and in prevention of reinfections. Cultures should be performed at weekly intervals for three or four weeks; if these are negative, the patient can be considered cured. It is common, especially in males, to have a slight mucoid urethral discharge for weeks or months even when the cultures are negative. This is regarded by some authorities as a nonspecific form of urethritis which is acquired at the same time as the gonococcal infection and it is said to respond to therapy with oxytetracycline. Until this view is better substantiated, it is probably best to regard the persistent discharge as a manifestation of subsiding inflammation which usually disappears spontaneously and requires no therapy. Retreatment is indicated in the small number of patients whose cultures remain positive. Treatment failures are not due to the development of penicillin-resistant gonococci and few, if any, cases fail to respond to a second course of therapy consisting of two to four daily injections. To be certain that the therapy has been effective in preventing syphilis, serological tests should be performed for four months.

If the prostate, seminal vesicles, or epididymis is involved, the patient should be put to bed and should receive 600,000 units of procaine penicillin two or three times daily for one or two weeks. When abscesses form in the prostate or epididymis or there is a failure to respond to penicillin after two or three weeks, surgery may be indicated.

The same general principles are applicable in the management of acute salpingitis. There is usually a prompt response to penicillin with subsidence of pain and a return of the temperature to normal within forty-eight hours. Except for the drainage of abscesses, surgery is not indicated in the acute stage. Resection of infected tubes, including all pelvic organs, is per-

is followed by the appearance of a purulent urethral discharge. The infection tends to spread posteriorly and involvement of the posterior urethra is indicated by cloudiness in the second glass of voided urine. Urinary retention may occur if the prostate is involved and infection of the seminal vesicles usually causes fever and pain which may radiate to various parts of the pelvis. Acute epididymitis is associated with severe pain and tenderness and the testicle may become swollen. Involvement of the epididymis is a serious complication which often leads to sterility. Following treatment the signs and symptoms gradually subside but a slight mucoid discharge may persist for several weeks.

In the female painful urination and vaginal discharge are the commonest early symptoms. Involvement of Skene's or Bartholin's glands is usually indicated by redness at the orifices but may lead to the formation of large painful abscess. The notion that most Bartholin gland abscesses are gonococcal in origin has been disproved in most instances they are caused by other organisms such as streptococci. Lower abdominal pain characteristically appears when the infection spreads from the cervix into the fallopian tubes. The symptoms of acute salpingitis often appear quite abruptly and must be differentiated from those of appendicitis, pyelonephritis and ectopic pregnancy. Acute pelvic inflammatory disease is readily diagnosed when there is a history of recent sexual exposure, tender adnexal masses are present bilaterally and gonococci can be demonstrated on cervical smears. These aids are often not present however and differentiation of this condition from other causes of lower abdominal pain may be very difficult. Surgical exploration is sometimes necessary to exclude conditions which require surgical management. Salpingitis tends to recur causing fibrosis and destruction of the pelvic structures. Abscesses form and pain and fever are present intermittently. The patient is usually sterile and surgical removal of all the pelvic organs may eventually be necessary.

**Complications.** The establishment of metastatic foci secondary to invasion of the blood stream by gonococci is relatively uncommon at the present time. Awareness that it can occur is important however since prompt recognition and adequate therapy often lead to complete recovery. Transient bacteremia may occur without causing symptoms or there may be a shaking chill followed by a silent period prior

to the appearance of symptoms caused by metastatic lesions. Occasionally gonococci may invade the blood stream repeatedly over a period of weeks or months causing fever, chills, arthralgia and a variable skin rash. This syndrome of *gonococcemia* is difficult to differentiate clinically from the commoner entity of *meningococcemia*. Rarely *endocarditis* occurs and runs the malignant course characteristic of acute rather than subacute bacterial endocarditis. In most cases there is no pre-existing valvular damage. The aortic valves are the commonest sites of involvement but next in order of frequency are the valves of the right side of the heart. It is often difficult to obtain positive blood cultures and too few proved cases have been reported in the past decade to assess accurately the results of penicillin therapy.

**Arthritis** is the commonest extragenital complication of gonorrhea. Formerly a common and crippling disease this condition is now so rare that only a few cases are seen each year even in the larger city hospitals. Arthritis occurred in 3 to 5 per cent of patients with gonorrhea in the prepenicillin days but the incidence is now probably not greater than one tenth of one per cent. The onset is usually sudden consisting of an acute migratory polyarthritis which occurs from one to four weeks following the initial infection. The knees, wrists and ankles are most commonly affected but any of the joints in the arms and legs may be involved. Rarely the infection may be limited to one of the less commonly involved joints such as the sternoclavicular or temporomandibular. Tenosynovitis occurs more frequently than in any other type of arthritis and is present usually about the wrists, hands and feet.

The course of gonococcal arthritis is extremely variable. Thin serous fluid may accumulate in several joints and in these cases it is often difficult to demonstrate bacteria in the joint fluid. There is usually a prompt response to penicillin therapy however and complete recovery occurs within a few weeks. In other instances the arthritis becomes monoarticular after several days and the joint fluid is then more likely to be purulent and to contain gonococci which are demonstrable sometimes on smear but more often by culture. Prognosis in this type of case is likely to be poor particularly when treatment is delayed. Return of function to normal is unusual and limitation of motion which may progress to bony ankylosis is common especially when the wrist and hand joints are

Identification of meningococci is based on morphology fermentation of glucose and maltose and immunological reactions. Four immunological types have been differentiated in the past by agglutination with specific antisera but cross reactions are frequent particularly between types I and III. For practical purposes therefore it seems advisable to consider only two immunological groups of meningococci: group I to include the old types I and III and group II to include the remaining types and atypical strains. Group I strains are encapsulated and many readily be identified immunologically by capsular swelling with homologous type specific antiserum. One strain in group II termed group II<sub>a</sub> is likewise encapsulated and thus may be similarly identified. Other serological methods of identification such as precipitation and complement fixation may be used but are generally less simple and satisfactory than agglutination and capsular swelling.

Substances termed "endotoxins" may be extracted from living or dead meningococci. Although the toxicity of such extracts for animals has been demonstrated there is little evidence of type or group specificity. The production of a true type specific toxin or "exotoxin" by the meningococcus has been reported but most authorities question its existence.

**Epidemiology.** Sporadic meningococcal infections occur almost constantly throughout the world. Epidemics tend to recur irregularly in five to ten year cycles superimposed on an annual seasonal increase the peak month of which is usually March in temperate zones. In the United States and Canada the reported incidence of meningitis has been slowly falling annually since 1953. The susceptibility of the general population is low and morbidity rates for clinically apparent disease are seldom higher than 10 to 1000 per 100,000 in the exposed population during epidemic periods. Infants and children are most frequently attacked in one series of 3557 cases 27 per cent of the patients were less than five years of age and 45 per cent were less than fifteen. The incidence is usually higher in males than in females. Race and color have no known influence on incidence or susceptibility. The higher rates reported among Negroes in certain urban areas have been attributed primarily to crowding. The exact incubation period is unknown but probably is between one and ten days.

The portal of entry of the organisms is the upper respiratory passages and trans-

mission from person to person presumably may occur by direct or intimate contact by airborne droplets or by articles contaminated with secretions of the respiratory tract. Even during severe epidemics however the majority of clinical infections have no apparent connection with one another and case to case spread is usually impossible to trace. Cultural surveys during periods of high incidence have shown that more than 90 per cent of the population harbor meningococci in the nasopharynx either constantly or intermittently during an outbreak without clinical evidence of infection (carriers). During interepidemic periods the organism may be recovered from less than 5 per cent of persons examined. Even under conditions of low carrier prevalence however a considerable proportion of the population will harbor meningococci at some time during a period of weeks or months since the respiratory tract flora is not static but changes constantly through acquisition of new bacteria and their subsequent loss.

**Morbid Anatomy.** In carriers or inapparent infections abnormal reactions are ordinarily not found. Meningococcemia is characterized by focal hemorrhages into cutaneous subcutaneous submucosal and synovial tissues. The fundamental lesion is vascular in character with endothelial damage inflammation of the vessel wall necrosis and thrombosis. The classic finding is rapidly fulminating meningococcemia the Waterhouse-Friderichsen syndrome is bilateral adrenal hemorrhage. Damage to the adrenal cortex may occur without hemorrhage (Banks).

Involvement of the central nervous system is characterized by meningitis which progresses from hyperemia and an increased amount of cerebrospinal fluid to a purulent exudate organizing if the disease becomes chronic.

**Pathological Physiology and Chemistry.** The present theory of the pathogenesis of meningococcal infections is that the bacteria enter the body through the upper respiratory passages and become implanted in the membranes of the nasopharynx and adjoining structures. Symptoms and signs of acute upper respiratory infection may then result. Direct invasion of the blood stream takes place from these sites and evidences of bacteremia appear. Dissemination of the meningococci is followed by metastatic lesions in various sites such as skin meninges joints eyes ears and lungs. The symptoms and signs are dependent on the site of localization. In meningitis two

formed in chronic cases only when there is failure to respond to conservative management over a period of eight to twelve months

Penicillin either crystalline or procaine is often administered in doses much larger than those specified. In the opinion of the writer this is rarely necessary. For patients who cannot be treated with penicillin because of sensitivity reactions tetracycline or one of its derivatives is effective. Two grams (0.5 gm. every six hours by mouth) are adequate for uncomplicated gonorrhea and the same dosage may be continued for one or two weeks when complications are present.

Gonococcal arthritis usually responds well to rest and penicillin if treatment is started early before the joint fluid becomes thick and purulent and tissue destruction has occurred. Because of the diffusibility of penicillin it is not necessary to inject the drug into the joint cavity. The involved joints should be kept in good position but prolonged immobilization is rarely indicated. The temperature usually remains elevated for seven to ten days but pain may persist for several weeks. Penicillin should be administered for about two weeks in most cases. Occasionally thick pus persists despite intensive therapy and surgical drainage may be necessary. Physical therapy is a valuable adjunct in promoting return of function in the convalescent stage. Failure to respond to penicillin

is often helpful from a diagnostic standpoint for as has been pointed out the differentiation of gonococcal arthritis from other forms of acute arthritis is often difficult. Large doses of crystalline penicillin G (5 000 000 to 10 000 000 units daily) should be used in the treatment of gonococcal endocarditis and meningitis.

**Prevention** Gonorrhea can be prevented by ingesting a single penicillin tablet (250 000 units) within three or four hours after exposure. Unfortunately this simple remedy has not been widely used so far by those who need it most. Programs of case finding and education leave much to be desired. Prompt treatment of contacts of males with acute gonococcal urethritis, the so called "speed zone technique" has been quite successful in some cities.

## Meningococcal Infections

**Definition** Meningococcal infections are manifestations of a specific infectious disease characterized by infection of the upper respiratory tract, invasion of the blood stream (meningococcemia) and focal involvement of various sites, notably the central nervous system (meningococcal meningitis, cerebrospinal fever, spotted fever or epidemic cerebrospinal meningitis). One or all of these features may be exhibited in a single patient. Meningitis has occurred sporadically and epidemically since its first recognition in Geneva in 1805 by Vieusseux and in the United States by Danielson and Mann in 1806.

**Etiology** The meningococcus (*Neisseria intracellularis*, *Diplococcus intracellularis meningitis*) was established as the causative agent by Weichselbaum in 1887. It is a gram negative coccus, variable in size and occurring singly or as biscuit shaped diplo-

cocci. Certain strains are encapsulated. The organism is fastidious in its metabolic requirements and will grow only on enriched laboratory media at body temperature. Meat infusion broth or agar containing 5 to 10 per cent of blood (rabbit, sheep or horse) or human ascitic fluid is an adequate medium. Chocolate agar prepared by heating fresh blood agar is especially suitable for initial isolation. Growth is augmented by incubating the cultures in an atmosphere containing 5 to 10 per cent of carbon dioxide. Meningococci are easily killed by chilling or drying so that prompt inoculation and incubation of all cultures is desirable. Because of the extreme susceptibility of meningococci to the sulfonamides, para-aminobenzoic acid in concentration of 5 mg per 100 ml should be added to media used for the culture of specimens from patients.

Early in the disease there may be a generalized mottled erythema which appears dusky if the patient is slightly cyanotic. Yellowish pink macules simulating the "rose spots" of typhoid wheals or nodules resembling erythema nodosum may appear before petechiae and ecchymoses. Careful search in strong daylight may be necessary to detect the early lesions. Occasionally vesicular pustular or bullous lesions are present. Superficial or deep ulcerations may result. A common site for the lesions first to appear is about the wrists and ankles but any area of the body may be involved including the conjunctivas and the mucous membranes. The hemorrhagic lesions fade to a brown rusty color three or four days after their appearance. New crops may appear often following chills so that the rash may present a varied appearance.

Other physical findings with the exception of splenomegaly are inconstant. Herpes labialis is found in about 10 per cent of the cases. Unless meningismus develops symptoms referable to involvement of the central nervous system are absent. The symptoms of metastatic localizations are usually self-evident depending on the site involved.

Laboratory examinations serve to establish the final diagnosis. Leukocytosis varying from 12,000 to 40,000 cells per cu mm is almost constantly present. From 80 to 90 per cent of the cells are neutrophils. Occasionally intracellular diplococci may be seen within the cells on a stained smear of capillary blood or of blood obtained directly from a skin lesion. Cultivation of meningococci from the blood furnishes final etiological proof. It should be emphasized that repeated cultures of the blood may be necessary to detect the meningococcus and that growth of the organism in liquid culture medium may be delayed. Other laboratory examinations give normal findings or results compatible with any febrile illness.

The subsequent course is dependent on therapy although approximately 20 per cent of the patients recover spontaneously after several weeks or months. Any of the complications and sequelae of meningococcal infections may develop.

Acute fulminating meningococcemia differs from the milder form chiefly in the rapidity of its progress and its overwhelming character. The onset is often abrupt and represents a dramatic departure from normal health with a shaking chill, severe headache, dizziness or vertigo, collapse or unconsciousness. Three forms may be differentiated (Banks):

(1) The adrenal form is characterized by massive purpura, low blood pressure, clear mental condition, rapid quiet respiration and overwhelming bacteremia. The extensive rash (Fig 24) involves skin and mucous membranes as well as internal organs, classically the adrenals. The temperature may be subnormal, normal or slightly elevated. Within a few hours circulatory collapse develops. Adrenal hormone replacement therapy may help to sustain these patients.

(2) The encephalitic form is characterized by rapidly developing coma, rapid stertorous breathing, a petechial but not massive purpuric rash and normal blood pressure.

(3) The mixed encephalitic-adrenal form is a combination of the two forms characterized by early deep coma, purpura and low blood pressure. Occasionally the pituitary gland may be damaged. Despite all efforts these illnesses usually are rapidly fatal.

Chronic meningococcemia is an infrequent form of meningococcal infection in which episodes of fever of a few days duration recur at intervals of days, weeks or months. Chills and arthralgic symptoms may accompany the bouts. Lesions of the skin or other characteristic signs may be absent or evanescent making diagnosis difficult. Repeated cultures of the blood may be necessary before the meningococcus is recovered. Unless recognized and treated, meningitis or endocarditis may develop.

Meningitis. This is the most characteristic and important of the metastatic localizations although constituting numerically a small percentage of the total meningococcal infections. The onset and symptoms in

FIG 22. Meningococcemia without meningitis in a 24-year-old male due to *Neisseria intracellulorum* group II treated with sulfadiazine.

factors—increased intracranial pressure and meningeal inflammation—are responsible for most of the characteristic clinical findings

The reasons for limitation of meningococcal infection to the nasopharynx and the blood in some persons or for its extension to other sites of the body particularly the meninges in other persons are not clear

Chemical alterations in meningococcal infections may be profound. Presumably they are initiated and maintained by metabolic and endotoxic substances from the bacterial cells together with the chemical by products of damaged tissue cells responsible for the phenomena of inflammation. Hemorrhagic manifestations are due to vascular damage. Other changes are similar to those in acute sepsis, namely dehydration, reduction in blood volume, altered acid base equilibrium from differential loss of acid or base, negative nitrogen balance, and fever. Meningismus may develop coincident with a relative increase in the ratio of the chlorides in the cerebrospinal fluid to the blood chlorides. In severe or overwhelming infections, cyanosis, circulatory collapse, and other signs of shock may develop, probably because of the combined action of bacterial endotoxins and tissue anoxia. If fluid intake is adequate, there is no decrease in plasma volume, no fall in plasma protein concentration, and no abnormal increase in capillary permeability to protein. Alterations in the blood similar to those of adrenal insufficiency, such as low sodium, elevated potassium, low chloride, and hypoglycemia, may be found and are consistent with an inadequacy of cortical secretion resulting from damage to the adrenal cortex.

**Symptoms.** The clinical manifestations of meningococcal infections can most conveniently be described by considering successive stages in the pathogenetic sequence, namely infection of the upper respiratory tract, bacteremia, and meningitis, or other metastatic localization. It should be emphasized, however, that this sequence of infection may not always be apparent clinically; the infection may extend so rapidly that the symptoms and signs of all the stages coexist in a given patient at the time he is first examined, or there may be such variations in the intensity of the symptoms referable to a single aspect of the disease that other aspects are overlooked.

Infection of the upper respiratory tract is numerically the most frequent type of men-

ingococcal infection. In the majority of patients, however, symptoms are absent or inconsequential, and infection can be detected only by culture of the nasopharynx. In the remainder, dryness or slight discharge from the nose, postnasal drip, soreness of the throat, and suffusion of the conjunctivas may be present. Physical examination reveals congestion or injection of the mucous membranes of the nose and pharynx, discharge from the sinuses, and rarely redness and edema of the tonsils. Exudate and regional adenopathy are ordinarily absent. Approximately 75 per cent of patients with generalized meningococcal infection give a history of preceding or coexisting nasopharyngitis. It has been postulated that in some of these patients the symptoms are due to infection with a virus, although the nature of such a virus has not been determined.

**Meningococcemia.** Bacteremic forms of meningococcal infections vary greatly from acute fulminating illnesses of a few hours' duration to indolent chronic infections lasting weeks, months, or even years. The progress of the infection may be steady and constant, or there may be relapses and recrudescences at varying intervals.

The commonest type of meningococcemia is a relatively mild, acute or subacute infection. Prodromal symptoms are ordinarily absent, with the possible exception of those of a mild upper respiratory infection. The onset is usually sudden, with feverishness, chilliness, occasionally frank chills, which may be recurrent, malaise, myalgia, and apathy. The presenting symptoms may be any of the above, but not infrequently the initial complaint will be recurrent fever, rash, arthralgia, acute polyarthritides, gastrointestinal upsets characterized by nausea and vomiting, or occasionally monoarthritis or conjunctivitis. The symptoms persist and often become exaggerated as the disease progresses. The fever may be remittent and irregular, with spikes to 102° or 103° F, or it may be intermittent in quotidian, tertian, or quartan fashion (Fig. 22). The pulse is full and strong, with a rate proportionate to the fever. Respirations are usually normal or only slightly elevated.

The most striking feature on physical examination is the rash, which is present in the majority of patients, particularly during epidemics. It appears soon after onset and may take a variety of forms, although the commonest lesions are petechial or purpuric, measuring in diameter from 1 or 2 mm to a centimeter and are pink to reddish blue in color (Fig. 23).

Early in the disease there may be a generalized mottled erythema which appears dusky if the patient is slightly cyanotic. Yellowish pink macules simulating the "rose spots" of typhoid wheals or nodules resembling erythema nodosum may appear before petechiae and ecchymoses. Careful search in strong daylight may be necessary to detect the early lesions. Occasionally vesicular pustular or bullous lesions are present. Superficial or deep ulcerations may result. A common site for the lesions first to appear is about the wrists and ankles but any area of the body may be involved including the conjunctivae and the mucous membranes. The hemorrhagic lesions fade to a brown rusty color three or four days after their appearance. New crops may appear often following chills so that the rash may present a varied appearance.

Other physical findings with the exception of splenomegaly are inconstant. *Herpes labialis* is found in about 10 per cent of the cases. Unless meningismus develops symptoms referable to involvement of the central nervous system are absent. The symptoms of metastatic localizations are usually self-evident depending on the site involved.

Laboratory examinations serve to establish the final diagnosis. Leukocytosis varying from 12 000 to 40 000 cells per cu mm is almost constantly present. From 80 to 90 per cent of the cells are neutrophils. Occasionally intracellular diplococci may be seen within the cells on a stained smear of capillary blood or of blood obtained directly from a skin lesion. Cultivation of meningococci from the blood furnishes final etiological proof. It should be emphasized that repeated cultures of the blood may be necessary to detect the meningococcus and that growth of the organism in liquid culture medium may be delayed. Other laboratory examinations give normal findings or results compatible with any febrile illness.

The subsequent course is dependent on therapy although approximately 20 per cent of the patients recover spontaneously after several weeks or months. Any of the complications and sequelae of meningococcal infections may develop.

*Acute fulminating meningococcemia* differs from the milder form chiefly in the rapidity of its progress and its overwhelming character. The onset is often abrupt and represents a dramatic departure from normal health with a shaking chill, severe headache, dizziness or vertigo, collapse or unconsciousness. Three forms may be dif-

ferentiated (Banks): (1) The *adrenal form* is characterized by massive purpura, low blood pressure, clear mental condition, rapid quiet respiration and overwhelming bacteremia. The extensive rash (Fig 24) involves skin and mucous membranes as well as internal organs, classically the adrenals. The temperature may be subnormal, normal or slightly elevated. Within a few hours circulatory collapse develops. Adrenal hormone replacement therapy may help to sustain these patients. (2) The *encephalitic form* is characterized by rapidly developing coma, rapid stertorous breathing, a petechial but not massive purpuric rash and normal blood pressure. (3) The *mixed encephalitic-adrenal form* is a combination of the two forms characterized by early deep coma, purpura and low blood pressure. Occasionally the pituitary gland may be damaged. Despite all efforts these illnesses usually are rapidly fatal.

*Chronic meningococcemia* is an infrequent form of meningococcal infection in which episodes of fever of a few days duration recur at intervals of days, weeks or months. Chills and arthralgic symptoms may accompany the bouts. Lesions of the skin or other characteristic signs may be absent or evanescent, making diagnosis difficult. Repeated cultures of the blood may be necessary before the meningococcus is recovered. Unless recognized and treated, meningitis or endocarditis may develop.

*Meningitis*. This is the most characteristic and important of the metastatic localizations although constituting numerically a small percentage of the total meningococcal infections. The onset and symptoms in

FIG 22. Meningococcemia without meningitis in a 24-year-old male due to *Neisseria intracellularis* group II treated with sulfadiazine.

FIG 24 Skin lesions in fulminating meningococcemia (Courtesy of Dr Worth B Daniels )

many cases may be indistinguishable from those of generalized infection in other cases the evidences of meningeal involvement predominate and in yet others both groups of symptoms appear to develop simultaneously even though there may be great variations in intensity and severity In addition to the manifestations of sepsis and the rash patients with meningitis present symptoms and signs of inflammation

and irritation of the meninges pain in the neck and back on forward flexion of the head muscular spasm stiff neck retraction of the head or even opisthotonos the presence of Kernig's and Brudzinksi's signs hyperesthesia hyperirritability and exaggerated reflexes Inequality of reflex response is not usual but may be found Involvement of cranial nerves may produce strabismus and deafness As the result of

increased intracranial pressure severe head ache nausea vomiting dilated or irregular pupils engorgement of the veins of the fundi choking of the disks irregular slow pulse and moderately elevated blood pressure may be prominent findings Cheyne Stokes or Biot's types of respiration may develop As the infection progresses restlessness and irritability may be succeeded by delirium or by convulsions of generalized or jacksonian type or the patient may become greatly depressed then somnolent and finally stuporous and comatose In infants the signs of meningitis may be no more than refusal of feedings vomiting or regurgitation diarrhea irritability and fever Convulsions and bulging of the fontanelles if present are extremely helpful signs

*Lumbar puncture* reveals slightly turbid to cloudy cerebrospinal fluid under a pressure of 250 to 300 mm or more of water The total cell count is elevated often to several thousand per cubic millimeter and the great majority of the cells are neutrophils Intracellular and extracellular diplococci can be found in variable numbers in stained smears of the sediment after centrifugation The total protein in the cerebrospinal fluid is increased and occasionally the fluid will clot after removal The sugar content is reduced Meningococci may be grown from the fluid by proper cultural methods

*The course* is extremely variable and is greatly influenced by therapy In untreated cases the temperature is so erratic that no typical fever curve can be described the symptoms persist and progress to early death or to chronic meningitis and delayed death or severe sequelae

*Complications* The complications of meningococcal infection and meningitis include intercurrent infection metastatic localizations and mechanical lesions in the central nervous system They may develop during the acute stage or later in the course Intercurrent infection of the respiratory tract due to agents other than the meningococcus may occur such as otitis media bronchopneumonia pleurisy herpes and influenza Bacteremic or metastatic complications include conjunctivitis panophthalmitis or other types of ocular infection otitis polyarthritus purulent monoarthritus (usually a late complication) pneumonia pleurisy pericarditis endocarditis myocarditis with cardiac enlargement and electrocardiographic changes orchitis epididymitis jaundice hepatorenal failure

transient albuminuria and hematuria and adrenal hemorrhage Infection in the central nervous system may produce the complications of transient paralysis hemiplegia neuroradiculitis encephalitis encephalomyelitis change in mentality glycosuria convulsions cranial nerve involvement cerebral thrombosis and brain abscess Organization of exudate in the ventricular channels and the subarachnoid space may mechanically obstruct the flow of cerebrospinal fluid and result in hydrocephalus The accumulation of subdural fluid of high protein content which may be encapsulated and resemble a subdural hematoma is a not infrequent complication in infants and young children Complications resulting from therapy may also occur

Permanent sequelae may result from almost any of the complications but the commonest are deafness ocular palsies blindness changes in mentality psychoses and hydrocephalus

*Diagnosis* The diagnosis of meningococcal infection depends primarily on differentiation from other acute systemic infections and other types of meningitis In any case final confirmation of the diagnosis must be based on bacteriological identification of the meningococcus During an epidemic all cases of fever of unknown cause and abrupt onset of marked prostration with or without fever of petechial or purpuric rash of drowsiness or coma and of meningitis should be treated as meningococcal infections even though organisms are not found in initial smears and cultures

Meningococcal infections in the early stages may resemble any acute systemic infection In sepsis due to pyogenic organisms such as staphylococci or streptococci there may be a preceding upper respiratory infection recurrent fever malaise arthralgia and leukocytosis A rash similar to that of meningococemia may rarely be present in such cases Final differentiation is accomplished by isolation of the organisms from the blood Meningococcal infections must also be differentiated from the acute exanthemata typhus typhoid and other enteric fevers subacute bacterial endocarditis influenza rheumatic fever and brucellosis

The diagnosis of meningococcal meningitis requires differentiation from meningitis of other forms of bacterial meningitis viral infections of the central nervous system myeloencephalitis due to bacterial toxins (tetanus botulinus) or chemicals and noninfectious processes such as sub

arachnoid hemorrhage · cerebral hemorrhage or thrombosis diabetic coma and uremia

In the majority of cases of *meningococcal meningitis* diagnosis is readily established by identification of the specific diplococcus in others the etiology may not be easy to determine when the patient is first seen but a number of procedures helpful in differentiation can be carried out The usual medical history should be obtained including a careful inquiry regarding recent localized infections and trauma to the head since these predispose to the secondary purulent bacterial meningitides Physical examination should include a careful search for diseases of the eyes and the upper respiratory passages and sinuses evidence of injury to the head and foci of infection in addition to thorough general and neurological examinations Complete blood counts should be made and cultures of the blood obtained Any foci of infection should likewise be cultured Urinalysis and determination of the blood nonprotein nitrogen aid in differential diagnosis and may indicate precautions to be observed in therapy

Lumbar puncture using aseptic technique should be performed as soon as possible and before chemotherapy is instituted After the initial pressure is determined cerebrospinal fluid should be removed slowly until the pressure is reduced to approximately normal levels The dynamics of the cerebrospinal fluid can then be determined by jugular compression to indicate the presence or absence of block or sinus thrombosis Examination of the cerebrospinal fluid should include the following appearance total cell count differential leukocyte count determination of sugar and protein examination of stained smears and cultures The chlorides may be determined if desired If no organisms are seen in the initial smears they may often be found in smears repeated after incubation of some of the fluid overnight

A tentative diagnosis can usually be made on the basis of a Gram stained smear the differential cell count and the sugar content of the cerebrospinal fluid If organisms are seen on the smear they may frequently be recognized by their morphology and staining reactions Caution should be exercised at this point however since even experienced personnel may be misled by overdecolorized or dead gram positive diplococci or other bacteria Final diagnosis depends on typing or culture and in the case of group I and II<sub>a</sub> meningococci a

direct quelling test may give immediate identification The leukocytes are almost entirely neutrophils in all the bacterial meningitides except syphilitic or tuberculous meningitis In the latter exceptions as well as in viral infections (lymphocytic choriomeningitis poliomyelitis and the viral encephalitides) mononuclear cells predominate except in the earliest stages of illness The sugar content is low in bacterial meningitides but is normal in viral infections In meningismus the fluid is usually normal with the exception of a relatively low protein and chloride content Erythrocytes and leukocytes are found in the proportion of their occurrence in blood in cases of subarachnoid hemorrhage The history other physical findings and special laboratory tests serve to differentiate myelencephalitis due to toxins or chemicals

**Prognosis** The present prognosis in meningococcal infections is enormously improved because of the efficacy of the sulfonamides as therapeutic agents In untreated cases of meningococcemia and meningitis the mortality in the past has varied from 20 to 90 per cent averaging about 70 per cent after the introduction of serum therapy it averaged approximately 50 per cent Since the introduction of the sulfonamides the case fatality rate has been reduced to 10 to 15 per cent Age is an important factor in prognosis since the greatest mortality despite adequate therapy occurs in patients less than two years and more than forty years of age In the Army during World War II the overall mortality was slightly less than 5 per cent and in some series of several hundred cases even less than 1 per cent In addition to a favorable age distribution in the Army the excellent physical condition of the patients early diagnosis and prompt therapy are responsible for these remarkable figures The prognosis must still be guarded in the acute fulminating cases with abrupt onset extensive cutaneous manifestations and circulatory collapse In spite of intensive therapy such illnesses usually terminate fatally Relapses recurrences and complications have been greatly reduced by chemotherapy and the prognosis for complete recovery is good The commonest permanent sequelae with adequate chemotherapy have been deafness cranial nerve paralysis mental deficiency and less frequently blindness and hydrocephalus

**Treatment** Sulfonamides are the agents of choice in the treatment of meningococcal infections The majority of cases treated adequately show marked and dramatic im-

provement within forty-eight hours. The meningococcus is highly susceptible to all the various derivatives but sulfadiazine is preferred because of its proved efficacy and low toxicity.

Patients with acute meningococcemia respond promptly to sulfadiazine given in an initial dose of 4 gm followed by 1 gm every four hours. Oral administration is usually feasible; parenteral administration as described below may be advisable initially if vomiting is frequent and persistent. The drug should be continued for two to five days after clinical and symptomatic recovery. In chronic meningococcemia more prolonged therapy may be required.

In cases of meningitis chemotherapy should be instituted as soon as the diagnosis of meningitis has been established and the proper cultures obtained. Parenteral administration of the drug is preferable for the first dose even though oral administration may be possible because of the rapidity with which an effective concentration is attained in the blood. The initial dose of 0.05 to 0.1 gm of sodium sulfadiazine per kg of body weight (or approximately 3.5 to 6 gm) should be given intravenously as a 0.5 per cent solution in physiological saline. The maintenance of an alkaline urine to prevent the precipitation of sulfadiazine (and its acetyl derivative) in the renal tubules and urinary tract has been advocated by some clinicians. Usually the urine will be rendered alkaline if the initial dose of sodium sulfadiazine (approximately 5 gm in an adult) is administered intravenously dissolved in 1000 ml of M/6 sodium lactate solution. The subsequent doses of sodium sulfadiazine may be given intravenously in 500 ml of M/6 sodium lactate solution. If the patient is unable to retain oral medication therapy should be continued by giving the same total amount daily in three equally divided doses administered intravenously at eight hour intervals or in two divided doses given subcutaneously at twelve hour intervals. Frequent determinations of the sulfadiazine concentration in the blood should be made to prevent overdosage. A concentration of 10 to 12 mg per 100 ml is desirable. Concentrations above 15 to 20 mg per 100 ml are not advisable since complications may result. After the first two days of therapy the majority of patients will tolerate oral administration. The same daily dose should be given in equally divided amounts at four or six hour intervals. When the sulfadiazine is administered by mouth it is necessary to give approxi-

mately 15 gm of sodium bicarbonate in divided doses each day in order to maintain an alkaline urine. Therapy should be continued for two to five days after complete clinical recovery. Dehydration should be corrected by the administration of approximately 3 liters of physiological solution of sodium chloride or for the average adult 6 per cent of the body weight. The additional daily intake should be sufficient to ensure a urinary output of more than 1000 ml. Approximately 3 liters will be necessary for the average person, half of which may be given as a 5 per cent solution of dextrose. Serum therapy is no longer used in the treatment of meningococcal infections.

Patients with acute fulminating meningococcemia and meningitis should be treated intensively and promptly without awaiting cultural confirmation of the diagnosis. Sodium sulfadiazine should be administered parenterally as outlined above. Penicillin may also be given. Supportive therapy directed toward the correction of adrenal insufficiency should be instituted if circulatory collapse seems imminent or has occurred (Cassidy). Optimal results should be produced by the administration of large doses of cortisone or hydrocortisone preferably intravenously together with intravenous norepinephrine to maintain blood pressure within normal limits (for further details see later section on Treatment of Adrenal Crisis). An intravenous infusion of 1000 to 1500 ml of physiological solution of sodium chloride with 10 per cent glucose should be given immediately. Additional fluid may be given to correct dehydration but an excess should be avoided. Oxygen therapy should be instituted and maintained as long as cyanosis or dyspnea is present. Blood transfusions have not been shown to be of definite value in this type of circulatory failure.

Penicillin has been used in the treatment of meningococcal infections but the results are less satisfactory than those obtained with sulfonamides unless such large doses as 1 000 000 units of sodium or potassium penicillin every two hours intramuscularly are employed (Lepper and others). This treatment schedule causes great discomfort to the patient and may increase the risk of serious reactions to the drug. Penicillin can not be considered as the equivalent of the sulfonamide drugs. For most patients sulfonamide drugs are preferable because of their powerful antimeningococcal action, their ease of administration, their demonstrated effectiveness and their low toxicity.

Penicillin may be of value however in patients who are sensitive to the sulfonamide drugs and possibly as an adjunct to chemotherapy in overwhelming infections. Successful therapy of meningococcal infections has been reported with other anti-microbial drugs. Apart from situations in which sulfonamides are contraindicated however, there are no demonstrable advantages in their use. In any event therapy should be continued until clinical and bacteriological recovery has occurred.

Certain laboratory tests, such as determinations of the sulfonamide concentration in the blood, hematological examinations and urinalysis, should be made as aids in controlling therapy. A concentration of 5 to 15 mg of sulfadiazine per 100 ml should be maintained in the blood; the concentration of drug in the cerebrospinal fluid will be approximately one third lower. Repeated determinations of hemoglobin, total and differential leukocyte counts and urinalyses aid in the early detection of deleterious reactions to chemotherapy. The level of non-protein nitrogen in the blood should be determined frequently if the initial concentration is abnormally high or if hematuria or anuria occurs. Blood cultures should be repeated if the fever persists, since continued bacteremia suggests the presence of endocarditis or other metastatic localization. Additional lumbar punctures are indicated if there is persistent increased intracranial pressure, failure to respond to adequate therapy or relapse.

Symptomatic and supportive treatment is as essential for patients with meningococcal infections as for those suffering from other severe infections. Sedation should be minimal yet sufficient to assure adequate rest. One of the barbiturates, chloral hydrate or paraldehyde is preferred. Approximately a month of convalescence will be required for complete recovery of the usual

case and even longer for severe illnesses.

The therapy of the complications of meningococcal infection is primarily that of the underlying disease, together with local or supportive measures as indicated. Should fever or signs of meningeal irritation recur, the most probable causes are recurrence of infection with the meningococcus, drug fever or infection due to another organism. Examinations of the cerebrospinal fluid and blood should be repeated. If meningococcal infection has recurred, the same treatment should again be instituted.

**Prevention.** Administration of as little as 2 gm of sulfadiazine will temporarily eradicate meningococci from the nasopharynx. Mass administration of the drug to both closed and open populations has accordingly been advocated as a control measure during epidemic periods and has apparently been successful (Macchiavello, El Sayed and Rahman). Isolation of patients with meningococcal infections is not necessary after twenty-four hours of adequate therapy with sulfonamide drugs, since the organisms are eradicated from the respiratory tract within this period. Such is not the case, however, when the other antimicrobial drugs are used.

## Bacillary Diseases

### Hemophilus Infections

#### PERTUSSIS

(Whooping Cough)

**Definition.** Pertussis is an acute respiratory infection caused by *Hemophilus pertussis*. Typically it consists of an attack of severe spasmodic coughing followed by a sudden forceful inspiration (the whoop). Thick, ropy mucus is often expelled by

coughing or by vomiting at the end of a paroxysm.

**History.** Although the earliest reference to the disease was probably made by Moulton in 1540, De Baillou in 1578 is credited with the first classic description of pertussis. Modern knowledge of the disease dates from 1906, when Bordet and Gengou identified the causative agent.

**Incidence.** Pertussis is sporadic and endemic to the more thickly populated com-

munities throughout the world. Epidemics prevail at intervals of two to four years. Though cases occur regularly during the summer months they are more numerous in winter and spring when complications are likewise more frequent. The peak of the incidence in the southern states occurs in May in the North in January or February. It appears to be more frequent among females. The communicability rate is high resembling that of measles and varicella. In family exposures it approximates 85 per cent.

Although pertussis occurs at all ages it is decidedly a disease of early life. About 85 per cent of all cases occur in children less than seven years of age and about one half of these are found in infants less than two years of age. Though maternal immunity may be passively conferred upon the newborn in certain instances infants younger than six months of age are very susceptible and are subject to a high mortality.

**Etiology.** *Hemophilus pertussis* discovered by Bordet in 1906 is the causative agent. It is a small gram-negative ovoid bacillus about  $0.5 \mu$  in length. It occurs in the respiratory tract in great numbers during the catarrhal stage of the disease but rapidly disappears during convalescence. Carriers are rare.

The disease has been produced experimentally by inoculation of suitable animals and man with pure cultures of the organism. Specific humoral antibodies result from the natural infection and from injection of specific vaccine. Immunity usually follows an attack of pertussis but a few bacteriologically proved instances of second attacks have been observed.

Other organisms such as *Hemophilus influenza*, *Brucella bronchiseptica* and *H. parapertussis* may cause infections resembling whooping cough. The last two of these are related to *H. pertussis* on the basis of a common minor antigen.

**Morbid Anatomy.** Catarrhal infection in the epithelium of the respiratory tract is always present. Here clumps of *H. pertussis* occur and beneath them develops the essential lesion of necrosis of the midzonal and basal portions of the bronchial epithelium with infiltration by polymorphonuclear leukocytes. Peribronchiolitis progresses into typical interstitial pneumonia. Edema and hemorrhage occur early as parenchymal lesions. Mucus pus and cellular debris within the alveolar spaces usually result from secondary infection although *H. pertussis* alone can produce the entire lesion.

In severe cases the brain is congested and contains punctate or larger hemorrhages. In rare instances encephalitis with cortical atrophy occurs.

**Pathological Physiology.** The essential departures from the normal physiological state observed in pertussis are (1) those related to disturbances in nutrition, (2) those resulting from changes in the pulmonary circulatory system and (3) those referable to the central nervous system.

Loss of appetite and vomiting cause weight loss. Excessive vomiting may produce gastric tetany. In infants diarrhea frequently occurs. Dehydration, starvation and emaciation impair nutrition to the extent that fatal secondary infections develop.

Irritation of the mucous membranes of the trachea and bronchi provokes the paroxysm. Obstruction of the lower air passages by mucous plugs induces atelectasis which along with interstitial pneumonia prevents proper oxygenation of the blood. According to Regan and Tolstouhrov a state of uncompensated acidosis results. Enlargement of the right side of the heart may result from increased impediment of the pulmonary circulation.

Anoxemia probably causes convulsions in many instances. Infancy pneumonia and severity of the paroxysms are important factors. Cerebral congestion, edema, hemorrhage and encephalitis are responsible for convulsive and other types of disturbances in the central nervous system. There is evidence that hypersensitivity is a causative factor in pertussis encephalitis. In rachitic infants convulsions may be due to tetany.

**Symptoms.** The incubation period though variable is usually from seven to fourteen days. In a series of 1123 cases Lawson found the mean duration of the period to be thirteen days. The course of the typical disease is six weeks in length representing three stages: the catarrhal, spasmodic and convalescent, each lasting approximately two weeks.

**Catarrhal Stage.** This period begins with a mild cough usually nocturnal which progresses in intensity and soon becomes diurnal. The mean duration of this period according to Lawson is eleven days. Coryza and sneezing are usually present and the appetite fails. The cough later resembles that of bronchitis. At this stage the physician is frequently consulted. In rare instances hoarseness is present and occasionally the disease begins with the features of acute obstructive laryngitis. There is often suffusion of the conjunctiva.

**Spasmodic Stage.** After about ten to four

teen days the cough becomes so aggravated that it occurs in series of explosive efforts in which the face becomes congested often cyanotic the tongue protrudes with each cough and the patient appears to strangle. Finally the attack ends with a sudden forceful inspiratory crow or whoop. Large amounts of thick ropy mucoid material are coughed up swallowed or vomited. Perspiration congestion of the neck and scalp veins mental confusion and exhaustion may follow the more severe paroxysms. In infants particularly may become so cyanotic and exhausted that they may require artificial respiration.

**Excitement** sudden thermal changes swallowing inhalation of irritating fumes tobacco smoke or even the occurrence of a paroxysm in a nearby patient may excite a spell of coughing. If a plug of mucus remains in contact with the hyperesthetic mucous membrane of the respiratory tract recurrent paroxysms very likely follow until it is dislodged. Epistaxis often occurs when the spasms are severe. Subconjunctival hemorrhages and edema of the lower eyelids occur frequently in cases with severe coughing.

**Convalescent Stage** The number and severity of the paroxysms gradually decrease vomiting becomes less frequent and the disease thus progresses into the stage of decline or convalescence. During this period the hilar and basilar rhonchi gradually disappear. For a period of weeks or months an intercurrent infection may cause the major symptoms to reappear even to the point of resembling a new attack.

It must be remembered that pertussis is a variable disease and may exist in a mild atypical form. The entire course may last only a few days. Proved cases have been known to last but from seven to fourteen days. Vomiting and the classic whoop may never occur. Very young infants particularly may have choking and cyanotic spells without the whoop.

**Complications and Sequelae** Bronchopneumonia is by far the most important complication. This is usually interstitial in type. Lobar pneumonia is rarely seen but occasionally confluent bronchopneumonia produces a lesion which clinically resembles that seen in the lobar type. Atelectasis is common because the blocking of a bronchus with mucus resulting in collapse of a portion of the lung and frequently leading to the erroneous diagnosis of pneumonia. Vesicular and interstitial emphysema occurs in practically all severe cases. Emphysema of the cellular tissue of the mediastinum

may result from rupture of air blebs on the surface of the lung. From the mediastinum the air may find its way into the subcutaneous tissues of the neck and even spread to other parts of the body. Cases with widespread subcutaneous emphysema are usually fatal. In one case of this type which later came to anatomical examination there was hyperleukocytosis of 257,000 cells per cubic millimeter. Pneumothorax may occur. Bronchial asthma and bronchiectasis may result from an attack of pertussis. An existing tuberculous lesion may spread during the disease although the effect of pertussis on tuberculosis is probably not as disastrous as was formerly believed. Unresolved pneumonia and pulmonary fibrosis are of common occurrence. Cardiac dilatation particularly of the right side is observed. It is most commonly associated with diffuse pneumonic involvement.

Otitis media is frequently encountered and is due to secondary invading organisms. Because of the tendency to suppurate the ears require the careful attention of the attending physician.

The hemorrhages of pertussis are mechanical in origin resulting from the venous congestion associated with severe coughing. Epistaxis and hemorrhage of the bulbar conjunctivas are common. Blood tinged sputum is a result of small erosive lesions in the trachea which occur during a paroxysm. Hemorrhage of the brain has been reported.

The most common neurological complication of pertussis is convulsions. They occur in about 8 per cent of hospitalized cases and are especially common in infants. The cerebrospinal fluid of those suffering from convulsions is usually normal.

Other neurological complications of pertussis are epilepsy mental retardation spastic paralysis myelitis and temporary or permanent visual disturbances.

Hernia usually umbilical and prolapse of the rectum are results of severe straining associated with the cough. Ulcer of the frenum occasionally results when the tongue is repeatedly thrust over the edge of the lower incisor teeth during the paroxysms.

**Diagnosis** Typical pertussis in the paroxysmal stage can be readily recognized. In the catarrhal period and in the atypical abortive form it is difficult to diagnose. Pertussis should be suspected in a person suffering from a cough of a weeks duration if examination of the nose throat and chest reveals no apparent cause for it. History of exposure may not be elicited.

The physician may be obliged to defer diagnosis until the cough becomes more definite. In such instances the patient should be isolated and a culture taken if the facilities are available. In doubtful cases inquiry should be made concerning previous injections of vaccine since mild atypical cases may occur as a result of the partial immunity thus conferred.

The most valuable of the laboratory diagnostic tests consists in the isolation of the organism from the upper respiratory tract. This may be accomplished by the cough plate technique or by the nasal swab method. Bacteriological diagnosis is particularly applicable during the catarrhal period when positive cultures may be expected in from 70 to 90 per cent of the cases. Only positive cultures are significant. A single negative culture does not exclude the disease.

A characteristic change in the leukocytes occurs during the late catarrhal or early spasmodic stage. This consists in a definite leukocytosis of from 15 000 to 40 000 white blood cells per cubic millimeter reflecting progressive increase in the absolute number of lymphocytes. Occasionally extreme degrees of hyperleukocytosis occur usually in cases complicated by pneumonia. This change in the leukocytes is probably due to direct stimulation of the hematopoietic tissues by *H. pertussis*. Failure to find this blood change does not constitute conclusive evidence against the existence of the disease.

In certain instances the finding of a significant titer of humoral antibodies in an unvaccinated patient may suggest recent infection with *H. pertussis*. Tests for agglutinins and complement fixing and mouse protective antibodies may be made with the patient's serum. Unfortunately humoral antibodies do not appear until the paroxysmal stage hence they are of little diagnostic value early in the disease. Attempts to develop a diagnostic skin reaction with various toxins and fractions of the organism have not been entirely successful.

**Prognosis.** During the period 1920 to 1953 the mortality from pertussis in the United States decreased from 12.5 to 0.2 per 100 000 population. In 1950 the fatality rate for the United States Registration Area was 0.93 per cent while in New York City (1951-1954) it was only 0.13 per cent. The highest death rate is in rural rather than urban areas. The younger the patient the more grave is the prognosis.

Prognosis should include recognition of

serious sequelae as well as the immediate fatality rate.

**Treatment.** *General Measures.* Normal room temperature and bed rest are desirable. Good nursing and hospital care are important in the care of seriously ill infants. Excitement and extreme changes in temperature provoke coughing. When vomiting is excessive small frequent feedings are advisable. Obstruction of the respiratory tract by excessive mucus may be relieved by careful suction.

Oxygen should be given to all patients with increased respiratory rates with or without cyanosis for it is one of the most important therapeutic agents for this disease. Small blood transfusions are indicated in cases complicated by anemia. A roentgenogram of the lungs and a tuberculin test should be obtained during convalescence.

**Medication.** Codeine, paregoric and phenobarbital are useful sedatives. Rectal insulations of a mixture of 2 to 8 ml of ether in 15 ml of olive oil every six to eight hours as necessary are effective for the control of severe paroxysms. The subcutaneous injection of 0.008 to 0.016 gm of sodium phenobarbital may prove helpful for the control of convulsions. Magnesium sulfate (0.06 gm per kg of body weight) may be injected intramuscularly for the same purpose.

**Specific Therapy.** Hyperimmune serum is indicated in severe cases. Hyperimmune human serum (20 to 40 ml) or the gamma globulin (5 to 10 ml) prepared from it serves similar purposes.

Chloramphenicol and the tetracyclines are about equally effective in dosages of 50 mg per kg of body weight per day divided into four doses. Because of its potential toxic effect on the bone marrow chloramphenicol should be used only in severe cases with careful observations of the blood count.

Penicillin is obviously indicated for the treatment of pyogenic complications.

In a previously vaccinated person additional injection of vaccine early in the disease is immunologically sound treatment.

**Prevention.** Young infants should be carefully protected from exposure to pertussis. The period of infectivity is about six weeks but the catarrhal stage is most dangerous.

Active immunization should start at or before the third month of age. The initial course of vaccine should be given in three monthly injections. The total dose should be 12 units contained in not more than 96 billion organisms in saline or 48 billion

organisms in alum precipitated preparations Stimulating injections (2 units each) should be given every two years until school age

To the exposed nonimmunized infant passive protection may be given by the intramuscular injection of hyperimmune human serum (10 to 20 ml) or gamma globulin prepared from hyperimmune human serum (2.5 to 5 ml)

## HEMOPHILUS INFLUENZAE INFECTIONS

The influenza bacillus has played two major roles in human infections (1) as a secondary invader in the influenza virus pandemic of 1918—Jordan has summarized the evidence for this influence and (2) as a primary agent in pyogenic infections

### PRIMARY H INFLUENZAE INFECTIONS

**Encapsulated *H influenzae*** Although six specific types of *H influenzae* a b c d e and f were differentiated by Pittman type b is responsible for almost all primary severe infections caused by influenza bacilli The pathogenic potentialities of encapsulated *H influenzae* as a primary agent are greatly modified by the age of the host The severe pyogenic infections occur almost exclusively in infants and children The decline in incidence with increasing age has been shown by Fothergill and Wright to be closely related to a greater bactericidal power of the blood of older subjects This

immunity is apparently the result of past contact with the organism

In Childhood Type b *H influenzae* is one of the commonest causes of severe infections in infants and children (Alexander and others 1942) Pediatricians are now familiar with several patterns of illness all of which are preceded by a nasopharyngitis The complications result from remote seeding consequent to a bacteremia as well as from spread to the ears paranasal sinuses larynx and lungs Of the severe infections meningitis obstructive laryngitis pyarthrosis and pneumonia occur most frequently

In Adults Immunity to these severe *H influenzae* infections while exhibited by most adults is not uniformly present Type b *H influenzae* pneumonia meningitis obstructive laryngitis and pyarthrosis are seen in adults but they occur very rarely

**PNEUMONIA** *H influenzae* type b pneumonia cannot be differentiated from pneumococcal pneumonia by clinical signs or the ordinary laboratory examinations The lesion may be lobar in distribution the blood shows a moderate leukocytosis and the erythrocyte sedimentation rate is significantly elevated Following adequate sulfonamide therapy the subsidence of infection is as prompt as in the average patient with pneumococcal pneumonia Penicillin in the usual dosage is not effective and on this basis *H influenzae* pneumonia may at times be erroneously classified as viral pneumonia

**MENINGITIS** *H influenzae* is the most frequent cause of meningitis in infants and children Prior to 1938 the mortality rate was virtually 100 per cent Patients with *H influenzae* meningitis do not exhibit clinical signs which can be distinguished from those of other varieties of pyogenic meningitis The clinical signs and changes in the cerebrospinal fluid vary with the stage of the disease and the severity of infection However prompt identification of the etiological agent can be made by bacteriological and serological procedures

**OBSTRUCTIVE LARYNGITIS WITH EPIGLOTTITIS** One form of severe rapidly progressing laryngeal obstruction is caused by *H influenzae* Lemierre was the first to separate influenzal laryngitis from other forms of croup he reported its occurrence in both children and adults In children *H influenzae* laryngitis presents a characteristic history and the patient a characteristic appearance The onset is sudden and the course fulminating Mild fever and dysphagia develop during an apparently in

nocuous respiratory infection. Dyspnea starts abruptly and increases within a few hours to such a degree as to make hospitalization imperative. The picture is that of a prostrated child with severe laryngeal obstruction usually demanding tracheotomy. The temperature is high. On examination of the pharynx there is diffuse erythema often with evident edema and when the tongue is pressed downward the enlarged distorted red and edematous epiglottis is easily seen.

**Bacteriological Diagnosis.** *H. influenzae* may usually be identified within thirty minutes when the infection is severe by the demonstration of capsular swelling of bacterial cells found in the appropriate biological fluid. In patients with pneumonia or obstructive laryngitis the organisms should be sought for in a concentrated suspension of nasopharyngeal mucus; they are found in cerebrospinal fluid in patients with meningitis in joint exudate in those with pyarthrosis and in the pleural exudate in empyema. When such direct identification is impossible growth in special media can usually be obtained in twelve hours (Dubos). In children bacteremia is a constant feature in all varieties of severe *H. influenzae* infections.

**Nonencapsulated *H. influenzae*.** A primary pathogenic role of nonencapsulated *H. influenzae* can seldom be established; this organism in fact is found frequently (30 to 50 per cent) in the nasopharynx of normal persons of all age groups. In infants it may occasionally cause meningitis or pneumonia. In adults it is a rare cause of subacute bacterial endocarditis and brain abscess. The Koch-Weeks bacillus *H. aegyptius* (Pittman) (which cannot be differentiated from *H. influenzae*) has been reported as the primary agent in epidemics of conjunctivitis.

**Treatment of *H. influenzae* Infections.** The therapeutic efficacy of sulfonamides, specific rabbit antiserum, streptomycin and chloramphenicol against *H. influenzae* is now well established. When the infection is sufficiently mild each of these agents can bring about recovery. On the other hand if the infection is severe each is limited in its therapeutic capacity; the combined action of two is required for successful treatment. The location, duration and severity of infection govern the number of agents which should be used simultaneously in a given patient. Experience with these agents in the various *H. influenzae* clinical patterns is well documented in childhood infections only, but there is every reason to

believe that the methods of treatment in this age group are applicable to adults (Alexander 1954).

In obstructive laryngitis sulfadiazine alone can cure most patients after an adequate airway is established by tracheotomy. Pneumonia can also be successfully treated with sulfadiazine alone. However, the risk of therapeutic failure is virtually eliminated by the initial use of a second effective agent, chloramphenicol or a tetracycline. In meningitis, pyarthrosis and empyema the combined action of two drugs is indicated. There are now sufficient data for comparison of three different therapeutic programs in meningitis: (1) type-specific rabbit antiserum and sulfonamides, (2) streptomycin and sulfadiazine, and (3) chloramphenicol and sulfadiazine. Any of the three can be expected to cure virtually 100 per cent of the patients who are treated early in the course of the disease. It has not been possible to show a significant difference in efficacy among these three pairs of agents. The ease with which optimal concentrations can be maintained in the cerebrospinal fluid by either the oral or parenteral routes and the rarity of injurious effects make the combined action of chloramphenicol and sulfadiazine the treatment of choice for meningitis and all other severe varieties of *H. influenzae* infections. When the oral route is used for chloramphenicol, 200 mg per kg is given daily in four doses (not to exceed 3 gm) when parenteral administration is necessary, 100 mg per kg (not to exceed 2 gm) is given each twenty-four hours in three doses. The dose in adults should not exceed 5 gm orally or 3 gm parenterally. Parenteral administration is recommended during the first twenty-four hours either by continuous intravenous drip using sulfisoxazole (Gantrex) as the sulfonamide or by the intramuscular administration of chloramphenicol and the subcutaneous administration of the 5 per cent sodium salt of sulfadiazine.

## HEMOPHILUS DUCREYI INFECTIONS

(Chancroid)

*Hemophilus ducreyi* was first described by Ducrey in 1889 in stained purulent material from soft chancres as minute gram negative bacilli 1 to 2  $\mu$  in length arranged in pairs chains or fish school formations. The microorganism cannot be cultivated on ordinary media. By special methods however growth of *H. ducreyi* is usually obtained from pus derived from infected patients provided that the lesion is not grossly contaminated by secondary invaders. Typical morphology on stained smear and characteristic growth are accepted by some as adequate evidence for diagnosis of *H. ducreyi* as the etiologic agent. Others require in addition a positive skin test, autoinoculations by rubbing the lesion fluid into the scarified skin of the forearm and typical histological changes on biopsy. The reliability of any one of these tests for diagnosis in a particular patient is open to question. The presence of characteristic clinical features and exclusion of syphilis, lymphogranuloma venereum, granuloma inguinale and herpetic infections by specific laboratory tests are necessary prerequisites for diagnosis of *H. ducreyi* as the causative agent.

*H. ducreyi* infection has assumed an important role as a venereal disease in the southern part of this country and in tropical regions of the world. During World War I about 10 per cent of all chancres were caused by *H. ducreyi*. Soft chancre or chancroid produced by *H. ducreyi* has a characteristic clinical appearance and history. After an incubation period of two to fourteen days following sexual intercourse there appears a small red papule on the genitals or surrounding skin which in a period of a few days goes through a purulent and then necrotic stage followed by ulceration. The ulcer is characterized by surrounding erythema and edema and by edges which become irregularly undermined. The induration which is typical of the syphilitic chancre is absent in chancroid. The lesions produced by *H. ducreyi* are frequently multiple as the result of autoinoculation. When untreated abscesses of the inguinal lymph nodes follow and are associated with constitutional signs.

Sulfonamides are effective treatment for *H. ducreyi* lesions. The tetracyclines, streptomycin and chloramphenicol have also been used with success. However as each of the latter agents shows some action against *Treponema pallidum* their use is

contraindicated unless the lesion proves resistant to sulfonamides and daily darkfield examinations on four successive days fail to demonstrate *Treponema pallidum*.

## Granuloma Inguinale

Granuloma inguinale is an indolent, granulomatous and ulcerative disease usually localized to the genitalia and caused by a pleomorphic coccobacillus *Donovania granulomatis*, the so called "Donovan body". Presumably the infection is customarily transmitted during coitus or other close bodily contact and the degree of communicability appears to be relatively low. The lesion tends to be single and may rarely appear on surfaces of the body other than the genitalia. Systemic infection, notably with the production of arthritis or osteomyelitis, has been reported. Usually the lesion appears on the genitalia or in the perianal area as a relatively painless nodular infiltration which soon breaks down leaving a sharply demarcated ulcer with friable granulation tissue at the base. On histological examination the lesion appears well vascularized and the site of considerable cellular infiltration, especially with polymorphonuclear leukocytes and monocytes. In appropriately stained tissue scrapings the causative microbe *Donovania granulomatis* may be seen to be situated principally within the monocytes, although smaller numbers of extracellular microorganisms can usually be identified. The lesion spreads by direct extension, is highly destructive to the skin and subcutaneous tissue and secondary infection with other microorganisms is common. Rarely, if sufficiently extensive, the process may cause elephantiasis of the genitalia.

There is nothing particularly character

istic about the lesions of granuloma inguinale and the early lesion is indistinguishable from those produced by *T. pallidum* *H. ducreyi* or other processes that involve the genitalia. The diagnosis can be established only by appropriate microbiological techniques and these should be employed whenever the physician encounters a genital lesion (or an indolent ulceration elsewhere) that is not clearly caused by some other process. Microscopy of deep scrapings or impression smears from the lesion of granuloma inguinale stained by the Wright method usually reveals *Donovania granulomatis* within the monocytes. The ease with which the microorganisms can be detected varies to some extent with the age of the lesion. In a relatively old lesion the scrapings should be made from the depth of the lesion and an extensive search of the smears may be necessary. The microorganisms can also be cultured in medium containing chick embryo yolk by methods originally developed by Anderson and her associates. Antigen prepared from capsular material of *D. granulomatis* has been employed in a complement fixation reaction and in a cutaneous reaction but these have not yet been developed to the point of general application.

Granuloma inguinale has been successfully treated with streptomycin, chloramphenicol and the tetracyclines. As initial therapy tetracycline may be employed in a total daily dosage of 2.0 gm administered by mouth in divided doses for a two week period. In unusually extensive lesions it may be necessary to continue the treatment for a longer period in order to attain complete healing. If relapse occurs or the lesions appear refractory to tetracycline treatment streptomycin (or dihydrostreptomycin) should be administered intramuscularly in a total daily dosage of 2.0 gm in divided doses for a two week period.

With respect to the prevention of granuloma inguinale no detailed information is available. It seems likely however that thorough washing of the genitals with soap and water immediately after sexual intercourse has a significant influence in reducing the probability of infection.

## Diphtheria

**Definition** Diphtheria is an acute infectious disease caused by a bacillus *Corynebacterium diphtheriae*. The primary lesion is usually located in the pharyngeal area (fauces, nasopharynx or larynx) and is characterized by the formation of a grayish pseudomembrane. The organism elaborates a specific soluble exotoxin which is responsible for the local cellular injury and the systemic manifestations of the disease.

**History** Although a diphtheria like disease was described by medical writers as early as the second century A.D. diphtheria was first established as a clinical entity by the publication of Pierre Bretonneau's classic monograph in 1826. In 1883 Klebs described the diphtheria bacillus. A year later Loeffler demonstrated its etiological relationship to the disease and in 1888 Roux and Yersin clarified the pathogenesis of the disease by their discovery of the specific exotoxin. The first effective antitoxin was produced by von Behring. In 1890 Schick introduced his skin test for determining susceptibility. In 1913 Active immunization first introduced by Theobald Smith and by von Behring received its greatest impetus from Ramon's demonstration in 1923 that formalin treated toxin (i.e. toxoid) represented a nontoxic antigenically effective immunizing agent. Today the disease occurs throughout the world. In recent years morbidity and mortality rates have shown a significant decline in western Europe and North America.

**Etiology** The causative agent of diphtheria *Corynebacterium diphtheriae* is a gram positive nonmotile nonsporulating bacillus which is characteristically club shaped and frequently beaded in appearance. In stained smears the organisms are usually found arranged so as to form sharp angles with each other giving the characteristic Chinese letter appearance. Diphtheria bacilli grow well on ordinary laboratory media containing peptones or tissue extracts. The commonest media used are Loeffler's coagulated blood serum and potassium tellurite agar. Virulent diphtheria bacilli are distinguished by the ability to elaborate and secrete a specific poisonous substance diphtheria toxin which is a true exotoxin. It is the cause of the tissue necrosis occurring in the course of the clinical disease. Chemically it is a complex protein but the mechanism of its action is obscure. So-called nonvirulent strains of *C. diphtheriae* fail to produce this toxin. Freeman and others have shown that the ability to produce toxin is frequently associated with infection of the bacterial cell with a lysogenic bacteriophage which under proper conditions can convert an avirulent non-toxin producing strain into a fully virulent toxin producing one. Three types of C

diphtheriae are recognized largely on the basis of their characteristic colonial formation on potassium tellurite medium and their distinctive fermentation reactions. All three types, *gravis*, *mitis* and *intermedius* produce the same toxin and the same clinical picture. The weight of evidence at the moment suggests that *gravis* strains are found associated most frequently with epidemic diphtheria, *mitis* and *intermedius* strains with the endemic disease.

**Epidemiology and Immunity.** *Corynebacterium diphtheriae* is essentially an obligate parasite of man; hence the human host represents the only significant reservoir of diphtheritic infections. The organisms may be transmitted directly or indirectly from one person to another. As the usual habitat of the organism is the upper respiratory tract, droplet infection is probably the commonest method of spread, although contamination of the hands, handkerchiefs and similar objects may play an important role. Discharges from extrathoracic sites of infection (such as superficial ulcers of the skin) are infectious. Although the organism may survive for a brief period outside the human body, spread of infection by contaminated dust appears to be a rare occurrence. A few milk-borne outbreaks have been reported.

Invasion and infection of the human body by the diphtheria bacillus is not always followed by the development of clinical disease. More frequently the organism multiplies in the mucous membrane linings of the air passages for a shorter or longer period without causing signs of illness. Presumably in such cases the carrier possesses a pre-existing immunity of greater or lesser degree which, although it does not prevent the actual implantation of the organism, does limit the amount of damage to the host's cells so markedly that no clinical manifestations develop.

Immunity against the clinical disease depends primarily upon the presence of antitoxin in the blood of the infected person. Although it is probable that upon occasion antibacterial mechanisms play a role in preventing the diphtheria bacillus from actually establishing itself in the throat of the human subject, nothing is known concerning the nature or specificity of the reaction. On the other hand, recovery from an attack of clinical diphtheria is associated with the appearance of appreciable amounts of antitoxin in the blood.

This antitoxin is formed in response to the direct stimulation of diphtheria toxin. It has the characteristics of a true antibody; it may be formed in response to either clinical or subclinical infection or as a result of artificial active immunization. Although it is produced relatively slowly in response to the primary stimulation, it appears rapidly and in large amounts following secondary stimuli. Even

though little or no antitoxin can be demonstrated at the time of the secondary stimulation, it may be transferred to other persons (naturally by transplacental passage *in utero*, artificially by transfusion) thereby conferring temporary passive immunity upon the recipient.

**Schick Test.** Although the accurate determination of antitoxin levels is a laboratory procedure, the Schick test will usually yield valuable information concerning the immune status of an individual. This test is performed by injecting into the skin of the forearm 0.1 ml of diluted diphtheria toxin. A positive reaction is characterized by the development of a variable area of redness at the site of inoculation over a period of 72 to 120 hours. The reaction reaches its height on about the fifth day after this it gradually fades, leaving an area of brownish pigmentation which may persist for some weeks. Such a positive reaction is associated with an antitoxin level in the circulating blood of less than 0.03 units of antitoxin per ml and is interpreted to mean that the patient is susceptible to the clinical disease. A negative Schick reaction signifies that the blood antitoxin level exceeds 0.03 units per ml and that the subject's chances of contracting clinical diphtheria are comparatively slight. The occasional negative reactor who does develop clinical illness usually has a mild attack.

In actual practice the diluted toxin is injected in one forearm while the other forearm is injected with a similar amount of the same material which, however, has been heated to 60°C for thirty minutes in order to destroy the toxin. This control is necessary in order to detect pseudo-Schick reactions due to products of growth of the diphtheria bacillus other than the toxin itself. The pseudo-Schick reaction is characterized by the development of erythema at the site of inoculation about eighteen hours after injection. This increases to reach its maximum intensity at twenty-four to thirty-six hours and then fades gradually to disappear completely within the next seventy-two hours. Such a reaction connotes allergy to some component of the injected material rather than absence of circulating antitoxin in quantities adequate to confer immunity. Thus four types of reaction are possible as is indicated in the accompanying table.

Babies born to immune mothers will give negative Schick reactions at birth owing to the transplacental transfer of antitoxin. This passive immunity wears off rapidly and by the sixth month, in the absence of artificial immunization, nearly all infants are susceptible to the disease as evidenced by the demonstration of a positive Schick reaction. From this point on there is a gradual rise in the proportion of persons giving Schick negative reactions as a re-

Reactions in Schick Test

TYPE OF REACTION	OBSERVATION				INTERPRETATION	
	Test 36 hr	Arm 120 hr	Control 36 hr	Arm 120 hr	Immunity	Sensitivity
Positive	—	+	—	—	Absent	Absent
Negative	—	—	—	—	Present	Absent
Pseudo	+	—	+	—	Present	Present
Combined	+	+	+	—	Absent	Present

sult of natural immunization usually following subclinical infection. In the absence of continued contacts with the diphtheria bacillus, the antitoxin level falls to a point where the person is again susceptible to the disease.

### Pathogenesis and Pathological Physiology

The usual habitat of the diphtheria bacillus is the upper respiratory tract of man. In a susceptible person the organism multiplies in the superficial epithelial cells of the pharynx elaborating and secreting the specific toxin in the process. The absorption of this toxin by neighboring cells initiates a process of tissue necrosis which furnishes conditions favorable to the growth of the organism which in turn produces more of the toxin. As the process continues it stimulates an inflammatory reaction on the part of the body leading to the formation of the typical diphtheritic membrane. The absorption of toxin into the general circulation results in a degree of prostration usually out of proportion to the relatively mild appearance of the local lesion at this stage. If the membrane involves the larynx and trachea either primarily or secondarily mechanical obstruction to the airway may develop and death due to suffocation may occur unless the oxygen lack is corrected by intubation or tracheotomy. The soluble toxin is carried in the general circulation to susceptible organs such as the heart and cranial or peripheral nerves. Cardiac failure may be the result of specific necrotic injury to the myocardium or it may be secondary to peripheral circulatory disturbances. The cranial or peripheral nerve involvement is presumably due to the direct action of the toxin on the nerve cells. The explanation of the relatively selective action of the toxin remains obscure.

Aside from the striking picture of the local lesion the pathological changes noted in fatal cases of diphtheria are relatively nonspecific. Grossly the heart, liver, kidneys and adrenal glands may show degenerative changes characterized microscopically by necrosis, fatty infiltration and parenchymatous degeneration.

**Clinical Manifestations.** Diphtheria is characterized by a relatively short incubation period—one to four days on the average with an outside limit of one week. The clinical manifestations depend first upon the severity of the process (which may show every gradation between a mild nearly inapparent infection and a highly malignant progressive one) and second upon the anatomical location of the primary lesion. The more important clinical types are faucial (or tonsillar), nasopharyngeal and laryngeal. Extrarespiratory forms of the disease such as ocular, aural and cutaneous diphtheria do occur but in general are of less importance.

In *faucial diphtheria* the process is limited essentially to the tonsillar area. The onset is abrupt and is characterized by moderate fever, chilliness, general malaise and mild sore throat. Swallowing is relatively painless. The pharynx is moderately injected and dull red in appearance. The pseudo membrane first appears as a thick gelatinous exudate confined to one tonsil. This spreads to the other tonsil and thickens up so as to give the typical dirty white or grayish yellow diphtheritic membrane. If the pseudo membrane is forcibly removed a raw bleeding surface is exposed beneath over which the membrane rapidly forms anew. Tonsillar swelling is usually present and frequently there is some enlargement of the cervical lymph nodes. If the tonsils are absent the membrane may be less characteristic. Often the process spreads to involve the uvula and soft palate which become edematous. If the process remains limited to the tonsillar area the clinical manifestations may be so mild that a definite diagnosis can be made only by isolation of the organism.

*Nasopharyngeal diphtheria* represents a spread of the original process from the faucial area to the uvula, soft palate, posterior pharyngeal wall and nasal mucosa. The membrane covering these areas presents a dirty yellow appearance in some instances it invades the anterior nares and actually protrudes through the external opening. Occasionally the middle ear may be invaded as well. Faucial edema is marked and there is usually a serosanguineous nasal discharge. Enlargement of the cervical lymph nodes is almost invariably present. The swelling may be so marked as to deserve the name bullneck. A characteristic diphtheritic odor is usually present as well as pallor and cyanosis. Marked toxemia is the rule and the patient is almost always prostrated. Oliguria, albuminuria, weak rapid pulse and high fever are prominent features. If recovery ensues sequelae are common. This form of the disease should not be confused with anterior nasal diphtheria in which the disease process is limited to the anterior nares. This latter is a relatively benign process with minimal toxicity and its importance is chiefly epidemiological rather than clinical.

*Laryngeal diphtheria* usually results from the spread of infection downward from the nasopharynx although the primary lesion may be in the larynx itself. It is a particularly dangerous form of the disease since the membrane and accompanying edema

produce mechanical obstruction of the air way giving rise to the classic diphtheritic croup. The first symptoms are hoarseness, dyspnea and a characteristic brassy cough. As the obstruction increases, dyspnea becomes more marked and ultimately cyanosis appears together with aphonia and expiratory and inspiratory stridor. As bronchial secretions accumulate behind the obstruction the accessory muscles of respiration are brought into play and the spasmodic attacks of severe dyspnea gradually become frequent and persistent. Unless the airway is restored by intubation or tracheotomy, death by suffocation ensues. Rarely the process involves the bronchial tree as well.

**Extrarespiratory Diphtheria.** Although diphtheria is usually a disease of the upper respiratory tract, other parts of the body may be the site of primary or secondary diphtheritic lesions. Thus wounds, sores and abrasions of the skin may become secondarily infected. During World War II a number of skin infections occurred among men serving in the tropics. These took the form of chronic nonhealing ulcers which developed at the site of minor abrasions. In the course of time a dirty grayish membrane appeared. The majority of these infections yielded *mitis* strains on culture. The relatively low percentage of sequelae suggests that the absorption of toxin from such wounds was not marked, while the fact that antitoxin usually gave disappointing results raises the possibility that these so-called tropical sores had a complex etiology.

**Ocular diphtheria** is a rare form of the disease; the conjunctivae are chiefly involved.

**Diagnosis.** The presumptive diagnosis of diphtheria must be made on clinical grounds without waiting for laboratory confirmation, since the importance of early specific therapy of the disease is so paramount. The cardinal features pointing to the diagnosis are (1) a comparatively painless pharyngitis involving the tonsils (or tonsillar beds) and frequently the uvula and soft palate as well, (2) a relative lack of redness in spite of the presence of a significant degree of edema, (3) the appearance of the characteristic membrane in the tonsillar area, and (4) moderate pyrexia. In severe cases, significant systemic manifestations occur in mild cases; however, the patient may feel well throughout while the throat may appear comparatively innocuous.

The laboratory diagnosis depends upon

the isolation and identification of the causative organism from the lesion. The throat or wound swab should be taken by an experienced person and sent to the laboratory without delay. Here a Loeffler's slant, a tellurite plate and a blood agar plate should be inoculated promptly. Although experienced workers can recognize the organism in a fair percentage of cases by smears made directly from the wound or throat swab, this procedure is not recommended for the average laboratory. The inoculated cultures may be inspected at the end of sixteen to twenty-four hours and a presumptive diagnosis made on the basis of characteristic colony formation and cellular morphology. Confirmatory evidence may be obtained by a study of fermentation reactions and whenever indicated, virulence tests should be carried out. Other laboratory findings include a moderate leukocytosis and a transient albuminuria in all but the mildest cases.

**Streptococcal tonsillitis and pharyngitis** are most often confused with diphtheria. In the former conditions the throat is usually a fiery red, the tonsillar exudate thinner and lighter colored, the fever higher and swallowing is markedly painful. Frequently the follicles in the faucial area are quite prominent. Upon occasion it may be impossible to differentiate the two infections without resort to laboratory means. Rarely a concomitant streptococcal infection may mask the underlying diphtheritic process. Other conditions which must be considered in the differential diagnosis are Vincent's angina, agranulocytic angina, infectious mononucleosis, post-tonsillectomy throat and exudative pharyngitis caused by an adenovirus.

**Complications.** The most important complications are related to the myocardium and the nervous system. Signs of myocarditis may appear as early as the second week of the disease, although the usual time of onset is somewhat later. They are characteristically associated with the severer forms of respiratory diphtheria. In general, those cases showing early myocardial involvement tend to run a graver course. The onset may be insidious, with rising pulse of poor quality, distant heart sounds, premature contractions and gradual cardiac enlargement. Less often cardiac failure may appear with little warning. Pallor, epigastric pain, vomiting and circulatory collapse are the usual signs and symptoms. Inversion of the T waves, delayed conduction time, bundle branch block and terminally ventricular flutter or fibrilla-

tion are the commonest electrocardiographic changes noted. Occasionally peripheral circulatory collapse occurs. In the absence of demonstrable cardiac damage recovery when it takes place is usually complete.

Postdiphtheritic paralysis affecting the cranial or peripheral nerves is a relatively frequent complication. The commonest form of cranial nerve palsy is *paralysis of the soft palate*. This makes its appearance in the third to fifth week of the disease and is ushered in by the development of a nasal twang to the voice and regurgitation of fluid through the nose upon attempted swallowing. Although the course is usually mild occasionally tube feeding may be required. The condition tends to clear up completely in the course of a week or ten days. *Ocular paralysis* may occur in the fourth to sixth week of the disease. The two commonest types are *oculomotor* affecting the external rectus of one or both sides thus resulting in a convergent squint and *trochlear* in which the power of accommodation is weakened or lost. Spontaneous recovery in the course of a week is the general rule. Rarer forms of cranial nerve palsies are *facial*, *pharyngeal* and *laryngeal* paralysis. The prognosis in these forms is good unless there is concomitant involvement of the respiratory muscles.

*Paralysis of the peripheral nerves* appears somewhat later than do the cranial nerve palsies; the usual time of occurrence for the former is between the fifth and eighth week of the disease. The commonest form is a *polyneuritis of the lower extremities* as evidenced by weakness or paralysis of certain muscle groups. Total loss of function is rare and sensation is unimpaired. Complete recovery over a period of a few weeks is the general rule. Less commonly the upper extremities, the neck and the trunk may be involved. Again in general the prognosis is good if however the intercostal muscles are involved there is danger of serious respiratory embarrassment particularly in the presence of diaphragmatic weakness or paralysis.

It must be emphasized that polyneuritis of diphtheritic origin may occur in the absence of faucial manifestations of the disease. During World War II it represented the most important sequela of so-called "wound diphtheria."

**Treatment.** The prompt administration of diphtheria antitoxin in adequate amounts is the first and most important step. Laboratory studies and clinical experience have demonstrated the importance of administering antitoxin as early as possible in the

course of the disease. Presumably the union between toxin and cell is a stable one which cannot be broken down by any practicable amount of antitoxin; the role of the latter is confined therefore to neutralizing unbound toxin circulating in the blood stream and other body fluids thereby protecting the undamaged cells which have not come into intimate contact with the toxin as yet. Antitoxin should be administered as soon as diphtheria is suspected on clinical grounds without waiting for confirmation from the laboratory. Attainment of the early treatment of the actual case of diphtheria is well worth the price of administering antitoxin unnecessarily to an occasional individual. In a severe case of diphtheria the prognosis depends largely upon how early an adequate amount of antitoxin can be administered.

There is no agreement among clinicians as to the amount of antitoxin that should be administered. A conservative scheme calls for 10 000 to 20 000 units for mild cases, 25 000 to 50 000 units for moderate cases and 50 000 to 100 000 units for severe cases. These figures are for the average adult but in actual practice age and weight are not often taken into account except among the very young. The total dose required should be administered at one occasion if possible. The route of administration may be intramuscular or intravenous. The latter route has the advantage of speedier absorption but in theory gives a greater risk of an overwhelming anaphylactic reaction. In general the intramuscular route is preferred for doses up to 20 000 units and the intravenous route for amounts above this. The subcutaneous route should not be used since absorption is relatively slow.

As diphtheria antitoxin is a foreign protein (horse serum) precautions should be observed against the occurrence of hypersensitivity reactions (i.e. anaphylaxis). These are (1) inquiry of the patient or of his family concerning a history of sensitivity to horses (or horse products such as dander etc.) or of previous exposure to horse serum and (2) performance of ophthalmic and intradermal sensitivity tests. In both tests a 1:10 dilution of antitoxin in saline is used. In the first method one drop of this dilution is dropped into the conjunctival sac and the eye is observed for the development of redness during the next thirty minutes. In the second method 0.1 ml. of the 1:10 dilution is injected intracutaneously in the forearm and the area is observed for the development of erythema.

wheals and similar reactions for the next half hour. If a positive reaction is obtained by either method it is *prima facie* evidence of sensitivity to the horse serum and hence antitoxin should be administered with caution. Desensitization is carried out by giving small doses of highly diluted antitoxin by the subcutaneous route at first and then gradually working up to the intramuscular and intravenous routes until the full dose has been given. Desensitization may be a tedious and nerve racking task but as antitoxin is the only specific therapeutic weapon available it is a process which must be carried out in cases in which sensitivity exists. Epinephrine must be at hand before antitoxin is administered by any route.

Since it has been shown that the administration of certain antimicrobial drugs (notably penicillin and erythromycin) helps to eliminate the causative organisms from the nasopharynx there has been an understandable tendency toward the routine use of one or more of these drugs in the treatment of all cases of diphtheria. Although diphtheria bacilli are susceptible to the action of these drugs *in vitro* the latter have no neutralizing effect upon the toxin thus they cannot be substituted for antitoxin. They find their greatest usefulness in the prevention of secondary infections and in the treatment of chronic carriers.

**General Management.** Complete bed rest is the first requirement. The period over which this should be maintained depends upon the degree of toxicity and the presence or absence of cardiac complications. In any event the return to activity should be gradual and guided by the careful observations of the physician. Local therapy of the throat is rarely needed in the absence of secondary infection although hot saline irrigations may be comforting. Dehydration should be treated with parenteral fluids containing dextrose. Careful watch must be kept for signs of developing cardiac or neurological complications. With these complications adequate rest is also the main feature of therapy. Digitalis appears to be without benefit in the treatment of cardiac complications. The patient should be kept isolated until two successive daily cultures are negative for the presence of virulent diphtheria bacilli.

**Prevention.** Active immunization represents the basic means at hand with which to control the occurrence of clinical diphtheria. Of the various preparations available fluid toxoid and alum precipitated toxoid are the most widely used in the United States. Both preparations consist of

a filtrate of a broth culture of diphtheria bacilli (i.e. diphtheria toxin) which has been treated with 0.3 to 0.5 per cent formalin at a temperature of 37°C until toxicity has disappeared. The resulting fluid toxoid is given in a primary course consisting of three injections (0.5 ml, 1.0 ml, 1.0 ml) at weekly intervals. If suitable amounts of alum are added to the fluid toxoid a precipitate forms. This alum precipitated toxoid may be resuspended giving a relatively purified immunizing preparation with a slightly superior antigenic potency because of a local stimulating effect of the alum on the tissues. A primary course consists of two 1 ml injections spaced a month apart. Against the obvious advantage of the alum precipitated toxoid must be weighed the fact that the greater sensitizing ability of this preparation may lead to unpleasant reactions upon subsequent reinjection. In addition a sterile abscess occasionally develops at the inoculation site as a result of the irritating action of the alum. Both fluid and alum precipitated toxoid are excellent immunizing agents at least 85 per cent of persons receiving a primary course may be expected to become Schick negative.

The primary course of active immunization should be administered within the first year of life preferably at about the third month. It may be combined with immunizations against tetanus and pertussis. One stimulating dose should be administered two years later and another at the time the child enters school. In susceptible older children or adults the possibility of a sensitivity reaction to the toxoid should be guarded against by the prior administration of 0.1 ml of a 1:10 dilution of fluid toxoid intradermally (the Moloney test). The development of a local reaction (best described as a severe pseudo Schick reaction) is warning that toxoid must be administered cautiously in multiple small suitably diluted doses. These reactions fortunately almost unknown before adolescence represent the great problem in immunizing adult population groups. Presumably they represent some degree of immunity and the mere carrying out of a Moloney test in a person giving a positive reaction may serve as an adequate antigenic booster.

**Passive immunization** is possible since the administration of relatively small amounts of antitoxin (1000 units) will confer protection for a period of two to three weeks. Because of the danger of inducing sensitization or of eliciting anaphylactic shock in a

person already sensitized to the foreign protein its use should be limited to immunization of persons peculiarly at risk of infection as for example nonimmunized children heavily exposed to virulent diphtheria bacilli. Inasmuch as the protection conferred by antitoxin is of such short duration active immunization with one of the toxoid preparations should be carried out at the same time.

In the event of an outbreak of diphtheria in a closed community (such as a school) the exposed persons should be observed closely in order that antitoxin may be administered at the first sign of suspicious illness. Routine throat cultures usually yield little information of practical value. The exposed persons should be given Schick and Moloney tests and those found susceptible and not sensitive should be immunized promptly with one of the toxoid preparations. Under special circumstances the administration of prophylactic antitoxin may be indicated.

### Clostridium Infections

**General Considerations.** The clostridia that are the anaerobic gram positive spore bearing bacilli are so widely distributed in nature—in soil and garbage, in dust of all kinds and in the intestinal tracts of most animals—that they are frequently found in pathological lesions. Although as might be expected they are particularly common in open wounds where they may produce various severe infections, these organisms can under suitable circumstances attack almost

any tissue of the body. Nevertheless their mere presence in a lesion is of little significance for the clostridia require special and delicately adjusted environmental conditions before they can produce manifestations of disease. In other words, and this cannot be too strongly emphasized, the clostridial infections of man are clinical and not bacteriological entities.

This fact has given rise to some difficulty in assessing the relationship of these organisms to disease, but in a broad way the many and varied pathological conditions due to the clostridia may be divided into two main groups: *neurotoxic* which includes botulism and tetanus, and *histotoxic* in which various tissues of the body, particularly the muscles, are invaded and destroyed. Although it is primarily the histotoxic infections of man with which this section is concerned, it should be pointed out that simultaneous infections with both histotoxic and neurotoxic clostridia can occur. Thus, particularly in war time, the association of gas gangrene and tetanus is not uncommon. *Cl. botulinum* has also been recovered from infected wounds and on at least three occasions has produced a fatal and clinically typical infection in this way. Finally, it should be mentioned that in addition to infection of traumatized tissues, one species, *Cl. perfringens*, has been implicated in the syndrome of acute gastrointestinal disease.

#### HISTOTOXIC INFECTIONS

##### GAS GANGRENE

Of the many different species of clostridia, only a small number are truly histotoxic and capable on their own of initiating severe and frequently fatal infections. Of this limited group of organisms the most important are *Clostridium perfringens*, *Cl. novyi*, *Cl. septicum*, *Cl. histolyticum*, and *Cl. bifermentans* (*sordellii*).

**Toxin Production.** All of these species of clostridia owe their pathogenic powers to the production of one or more potent exotoxins. These exotoxins are among the most powerful poisons known and are (with one minor and unimportant exception) entirely species specific. This point is of considerable practical importance in that the antitoxin prepared against *Cl. perfringens* is quite useless in combating an infection with *Cl. novyi*. Moreover, all the clostridia mentioned probably produce several different toxins. *Cl. perfringens* elaborates no less than twelve, *Cl. novyi* at least six, and *Cl. histolyticum* three, and there can be little doubt that more toxins remain to be discovered.

ered. However it is fortunate from a practical point of view that in any one species there appears to be but one single toxin of overriding importance in the genesis and progression of the disease and it is against this toxin that the appropriate antiserum is prepared. It should be mentioned here that a classification of *Cl. perfringens* and *Cl. novyi* into subspecies has been made in recent years on the basis of the various toxins produced or the different combinations of the same toxins: thus six types of *Cl. perfringens* A, B, C, D, E and F and three types of *Cl. novyi* A, B and C are now recognized. So far as human infections are concerned only *Cl. perfringens* types A, D and F and *Cl. novyi* types A and B are of interest to us. Finally it must be pointed out that certain of these toxins including some of great importance have been shown to be enzymes and that their specific substrates have been identified. This of course is a discovery of the greatest importance not only for our understanding of clostridial infections but for our investigation of disease processes in general.

**Mechanism of Production of Gas Gangrene.** It has already been stated that clostridia require special environmental conditions within the host before they can produce their pathological effects—indeed before they can even grow. Although it is known in a broad way what these essential factors are, detailed knowledge of this complex problem is still meager. The fundamental point to be borne in mind is that all these organisms are strictly anaerobic and will grow and produce their toxins only under conditions of markedly reduced oxygen tension. In the animal body such conditions may be achieved by various means: the prolonged application of a tourniquet, the pressure of a tight plaster, slight trauma, the presence of necrotic tissue in a wound, the occurrence of foreign bodies such as earth shell fragments or clothing and even necrotizing lesions due to aerobic organisms. Any of these situations is sufficient to permit germination of clostridial spores, the multiplication of the clostridia and the elaboration of toxins. Once the toxins have been produced the process is relatively simple. The toxin diffuses out into the surrounding tissues, kills them and so permits the organisms themselves to spread into new areas of reduced oxidation-reduction potential. There the process is repeated and so the disease continues to spread, gaining momentum and severity as it progresses.

That is the process in broad outline; of the details we are far less certain. In the

case of *Cl. perfringens* the organism most studied it seems clear that the alpha toxin is the element of prime importance. This has been shown to be a *lecithinase* which can readily kill tissue cells by attacking the lecithin present in the cell wall. Diffusion through the entire infected area is aided by the production of a *collagenase*, a *hyaluronidase* and a *fibrinolysin*, each of which can break down certain of the binding elements in the tissues. Although fully toxic strains of clostridia may be found multiplying in the depths of many wounds only when these organisms invade muscle tissue do they become really dangerous. The reason for this anomaly is far from being understood, though various hypotheses have been advanced in recent years. Indeed we are as yet uncertain of the ultimate cause of death in gas gangrene.

Destruction of muscle tissue should not in itself be fatal, yet it may be safely said that every untreated patient with gas gangrene will surely die. For this reason it has generally been assumed that death has been due to the toxins gaining access to the blood stream and then lodging in various ill defined vital centers. There is little evidence of such a process and it has been suggested that the lesion is essentially a local one, analogous to the crush syndrome and similar sterile destructive lesions of muscle. Final proof of this thesis is lacking.

**Pathological and Clinical Features.** Pathogenic clostridia may be found in any traumatic lesion but so far as man is concerned three main types of infections may be discerned: *simple contamination*, *anaerobic cellulitis* and *anaerobic myositis*. However these are not strictly circumscribed clinical entities; they are rather the most obvious stages in a continuous infectious process.

Little need be said of *simple contamination* for in the majority of wounds the presence of clostridia is quite unsuspected on clinical grounds. In *anaerobic cellulitis* on the other hand the anaerobic bacteria find conditions more suited to their needs and proliferate more widely, producing gas in the tissues both by a proteolytic and a saccharolytic process. The muscles as the name indicates are not invaded. The condition usually develops three to six days after injury, is of gradual onset and is unaccompanied by any severe signs of systemic upset. Pain is usually absent. Indeed by far the most obvious clinical signs are the presence of gas, foul odor and a thin, brownish seropurulent discharge.

In *anaerobic myositis* or true gas gan-

grene the process is far more acute and severe. The onset is usually sudden with an incubation period from as little as six hours up to three days after injury has been sustained. The most important and usually first symptom is pain in the affected area rapidly increasing in severity. This is accompanied by tachycardia, tachypnea and a fall in blood pressure. Some elevation of temperature usually is seen but the degree of fever is not related to gravity of the illness. On early inspection the skin is pallid and may be tense and shiny because of underlying edema. The wound exudes a brownish or blood tinged serous discharge with a foul odor. At this stage there is often no evident crepitation since this may be masked by accumulating fluid in the tissues. Actually the amount of gas produced is rarely so pronounced as the name of the disease would indicate. As progression occurs the skin assumes a dusky or bronze appearance and finally if the patient survives long enough it becomes deeply discolored and exhibits vesicles filled with dark red liquid which tend to coalesce. Herniation of muscle through wounds or incisions may result from increased pressure within the tissues. In later stages of the disease prostration is a dominating feature often accompanied by a peculiar apathy or indifference on the part of the patient. Stupor, delirium or coma may occur.

The abnormal changes in involved muscle can best be observed at operation. These consist of swelling, loss of contractility and alteration in color varying from pallor to a deep red mottling. Bubbles of gas frequently can be expressed by manipulation.

**Uterine infections** usually caused by *Cl. perfringens* probably represent the most common form of gas gangrene encountered in civilian practice. These infections ordinarily result from attempted criminal abortion but they may also follow prolonged labor or instrumental delivery. The course is similar to that already described except that bacteremia and massive hemolysis are more frequent complications. Intravascular hemolysis which occurs in many cases is generally associated with acute renal failure caused by a lower nephron type of nephrosis. Although some writers have stated that hemolysis never happens without invasion of the blood stream by *Cl. perfringens* the complete picture of shock, anuria and hemolysis may be seen in the absence of demonstrable bacteremia whereas patients with positive blood cultures may show no evidence whatsoever of either renal damage

or a hemolytic reaction. The fatality rate in uterine infections continues to be high since many patients who survive the acute phase succumb later to the effects of renal insufficiency.

**Diagnosis.** Gas gangrene is a clinical and not a bacteriological entity and diagnosis rests primarily on the appraisal of clinical phenomena already described. The most important of these are pain, edema and the general condition of the patient. It must be emphasized that other types of infection can cause the formation of gas in tissues so that its demonstration by roentgenography or the presence of crepitation does not specifically incriminate clostridia. Bacteria of the genus *Aerobacter* or *Escherichia* may be responsible for gas production and indeed within certain limits it can be said that cases with the most obvious and extensive early signs of aerosis are among those less likely to have gas gangrene.

Most observers agree that stained smears of the exudate from wounds or from the cervix when the uterus is implicated give important diagnostic information if they reveal typical gram positive bacilli in large numbers. Roentgenographic examination also may be helpful in incipient cases involving the extremities by disclosing the presence of gas and its spread along fascial planes.

**Treatment.** As is prevention, treatment is almost exclusively the province of the surgeon. The operative procedures generally consist of multiple incision and fasciotomy for the drainage of fascial compartments and open amputation if necessary. Among females with septic abortion curettage is usually performed in early cases and hysterectomy is not done unless there is clinical evidence of perforation of the uterus. In advanced cases hysterectomy has been associated with a high operative mortality.

Supportive measures are of great importance especially those designed to alleviate shock by the administration of blood, plasma, fluids and electrolytes so as to maintain blood volume and arterial pressure. Careful attention to these details of the therapeutic program is essential particularly in patients with renal failure and anuria. Antimicrobial drugs must be given. Penicillin is the agent of choice in doses of no less than 1,000,000 units every three hours in addition since mixed infections are frequent it is advisable to give one of the tetracyclines in a minimal dose of 0.5 gm every twelve hours preferably by the parenteral route. The efficacy of polyvalent gas gangrene antitoxin is questionable.

Nevertheless in severely ill patients the administration of 40 000 units of antitoxin intravenously every six hours is advocated provided that cutaneous tests for sensitivity to the serum have been done beforehand and are negative

**Prevention** Prophylaxis is almost entirely a surgical problem and rests upon the well established principles of prompt treatment after injury adequate removal of devitalized tissue and foreign bodies and proper supportive management Gas gangrene antitoxin is of no value in prevention nor should any reliance be placed on antimicrobial drugs In the handling of surgical patients tourniquets should be used cautiously and bandages or plaster casts must be applied carefully so as to avoid interference with the circulation Toxoids for active immunization are still in the experimental stage

#### CLOSTRIDIAL GASTROENTERITIS

Quite apart from these traumatic infections it has recently been established that *Cl perfringens* may also be involved in various gastrointestinal diseases

The simplest of these is a mild gastroenteritis differing in no way from food poisoning due to other bacterial species An aberrant form of *Cl perfringens* type A has been implicated in this condition it has been isolated from the suspected foods from the stools of patients and in volunteers has produced a similar clinical picture

A much more severe infection is *enteritis necroticans* in which there is an acute regional gangrene of the small intestine particularly of the jejunum This disease first appeared in Northwest Germany toward the end of World War II and by 1946 several hundred cases were known to have occurred in this area Essentially similar cases have since been reported both in England and the Americas There can be little doubt that the exciting agent is *Cl perfringens* type F This organism differs from the classic type A in producing relatively little of the alpha toxin (the lecithinase) but large amounts of the beta toxin The beta toxin it may be added is a hemolytic necrotizing and lethal factor known to be of importance in various enterotoxemic diseases of domestic animals Infection apparently occurs by the ingestion of contaminated food stuffs of which by far the commonest have been canned or preserved fish and meat The signs and symptoms of the disease are those of any similar acute lesion of the small intestine

so that the specific diagnosis has as a rule been made only at operation or more commonly at autopsy The fatality rate is high and treatment has usually consisted of supportive measures together with the oral administration of various sulfonamide preparations Serum therapy appears to have been of little value but the data are insufficient for a final evaluation Much the best results have been obtained by surgical resection of the affected areas of the gut but for technical reasons this is not always possible

Several reports of gastroenteritis apparently caused by *Cl perfringens* type D have also been published but such cases are distinctly unusual This clostridial species has long been known to be the cause of enterotoxemic disease in sheep It may also produce a similar disorder on rare occasions in man generally as a complication of damage to the bowel from other causes such as intestinal obstruction Epsilon toxin elaborated by the microorganism is believed to be an important factor in the pathogenesis of the enteritis

#### NEUROTOXIC INFECTIONS

##### TETANUS

**Definition** Tetanus is a neuromuscular disorder often referred to colloquially as lockjaw which is caused by a specific exotoxin of the infectious agent *Clostridium tetani*

**History** The disease has been recognized as a clinical entity since antiquity especially as a sequel to wounds sustained in combat but definitive knowledge of its nature and of means for its prevention and treatment was not acquired until the close of the nineteenth century Nicolaier in 1884 produced tetanus by injecting animals with samples of garden soil and described a bacillus resembling *Cl tetani* at the loci of inoculation However the microorganism was not isolated in pure culture until 1889 by Kitasato In 1890 von Behring and Kitasato published their classic report of successful immuni-

zation by repeated small doses of toxin and the neutralization of toxin by specific antiserum this great discovery laid the foundation for all subsequent work on immunological methods of prophylaxis and treatment. Evidence for the central action of tetanus toxin advanced by Marie and Morax in 1902 and by Meyer and Ransom in 1903 was subsequently challenged by Abel and his associates but recent studies by Wright Brooks and colleagues have fortified the earlier views. Ramon was responsible for the introduction in 1925 of tetanus toxoid for active immunization and for procedures whereby toxoid and antitoxin may be standardized.

**Etiological Agent** *Clostridium tetani* is a strict anaerobe and one of the few pathogenic microorganisms which may be identified with reasonable certainty on morphologic grounds alone. This is owing to the fact that in sporulating forms the spore is located terminally thus giving a characteristic "drumstick" or squash racket appearance to the cell.

The many studies on resistance of tetanus spores to heat and chemical agents have given varying results. It may be concluded however that none of the antiseptic agents employed clinically can be relied on to devitalize spores nor is simple boiling an entirely safe procedure. Autoclaving at 120° C for 15 minutes is the best method for sterilizing potentially contaminated instruments and equipment.

Although ten distinct antigenic types of *Cl. tetani* have been recognized by differences in their flagellar antigens all of them fortunately elaborate the same antigenic type of exotoxin which may be neutralized by a single antitoxin. The toxin has been isolated in crystalline form and is a protein with molecular weight of approximately 67 000. Next to botulinum toxin it is the most powerful poison known, each milligram of nitrogen corresponding to about 75 000 000 guinea pig MLD units. In solution the toxin is unstable and converts spontaneously to toxoid apparently by molecular dimerization; this conversion is accelerated and driven to completion by 0.4 per cent formalin.

**Epidemiology** Although tetanus is relatively uncommon the responsible agent is widely found in nature, its chief distribution being in the soil and in the gastrointestinal tract of man and a wide variety of animals. In fact its occurrence elsewhere may be said generally to depend on contamination from either of these two sources. There seems to be little doubt that a direct relationship exists between the extent to which soil is cultivated and its degree of contamination by tetanus spores. The population density of man and animals

as well as climatic conditions, terrain and types of soil is also an important factor. These points are exemplified by the fact that *Cl. tetani* has rarely been recovered from virgin soil or from areas of wasteland while a high percentage of positive results has usually attended the investigation of samples from urban and agricultural communities.

Studies of the carrier rate of *Cl. tetani* in the intestinal tract of man have yielded widely divergent results but have served to show that rural inhabitants, especially farm workers, harbor the microorganism much more frequently than do city dwellers or persons of sedentary occupation. These findings illustrate the epidemiological significance of sanitary conditions and of contact with horses and cattle.

As might be expected from its natural habitat and general distribution, *Cl. tetani* has been frequently isolated from the surface of the human body and occasionally from the oral cavity. It exists not uncommonly in house dust and has been recovered with disturbing ease from the floors of operating rooms where it probably was introduced by footwear. Plaster of Paris and surgical dusting powders have also been found to be contaminated.

In spite of the ubiquity of the etiologic agent the incidence of tetanus is for the most part remarkably low. For example, during the five year period ending in 1955 an average of approximately 500 cases were recorded annually in the United States, although doubtless others were not reported. This represents a considerable decline in incidence over the last two decades which probably reflects the shift of population toward cities, the general improvement in medical and surgical care of injuries and the greater use of tetanus toxoid as part of the immunization program in childhood.

A recent survey of tetanus in the United States for 1947-1955 showed that the incidence was highest in the South and that throughout the country the mortality rate among nonwhite persons was 5 to 6 times greater than in the white population. It was also found that more deaths occurred in children less than one year of age than in any other age group. These observations serve to emphasize the correlation of the disease with poor sanitation and inadequate medical services.

**Pathogenesis** It is well known that tetanus almost always results from some sort of injury, occasionally of the most trivial nature. For instance, in addition to tetanus

following war wounds highway accidents burns and other major types of trauma the disease has supervened after hypodermic injections smallpox vaccination the peck of a hen an insect bite and so on In occasional cases particularly among children it may be impossible to determine which of several minor injuries may have been responsible while in some patients no wound at all may be discovered

The all important feature of the initial event is that spores of *Cl tetani* must be deposited or exist already in tissues where the conditions are properly altered to suit its exacting metabolic requirements In general this means an area where the tissue has been devitalized and the oxidation reduction potential is properly poised to permit multiplication and toxigenesis The infection itself once started remains remarkably well localized at the original site since the invasive powers of the micro organism appear to be even feeble than those of *Corynebacterium diphtheriae* This fact incidentally is responsible for the former advocacy now outmoded of local excision or even amputation as a part of treatment

The disease proper is unquestionably caused by tetanus toxin but the mechanisms whereby it is absorbed and produces its effects are still largely unknown The early work of Marie and Morax and of Meyer and Ransom led to the theory that the toxin acted centrally in the nervous system rather than peripherally in the affected muscles and that it gained access to motor cells of the spinal cord by a centripetal spread via regional nerve trunks In cases of local tetanus it was assumed that the amount of toxin released was relatively small and that involvement of the cord was confined to the anterior horn cells mediating the regional reflex arcs It was also assumed that generalized tetanus represented a further spread of toxin by neural pathways in the cord itself to involve the motor areas more widely These concepts were challenged by Abel and his associates in a series of papers about 1935 in which experimental evidence was adduced that the toxin had a peripheral rather than a central action and was distributed by the blood stream rather than by nervous channels Since then additional support for both points of view has been brought forward from various sources but during the past few years the work of Wright Brooks and colleagues has convincingly shown the probable correctness of the first theory This work is too extensive to be described here

and the reader is therefore referred to the original references

The mode of action of tetanus toxin is entirely unknown No substrate for the toxin has been found attempts to demonstrate anticholinesterase activity have given negative results and no effect on production of acetylcholine has been clearly shown Certain investigators have claimed that the toxin acts as an enzyme to release a hypothetical substance with strychnine like activity but this suggestion does not seem to deserve serious consideration

**Morbid Anatomy** Tetanus toxin fails to produce any recognizable pathological lesions in the tissues it affects nor do any specific changes occur at the site of infection by *Cl tetani* In certain cases fractures or muscle disruptions may occur as the result of tetanic spasms

**Incubation Period** The incubation period in tetanus ranges from about three days up to four weeks and in exceptional cases even longer It should be stressed that the severity of tetanus and hence its outcome are related to the period of incubation cases with onset less than one week after injury having in general a more fulminating course This fact should be borne in mind in anticipating the therapeutic management of patients

It should also be noted that the incubation period may sometimes be extremely protracted in the sense that infection may be regenerated from spores which have resided in tissues for months or even years A case is on record in which tetanus developed fourteen years after an original war injury and in another *Cl tetani* was recovered from a hysterectomy scar ten years following postoperative tetanus Numerous accounts of shorter periods of latent infection have appeared In traumatic surgery especially of war wounds reoperation at the site of earlier injury may reactivate dormant spores and care should be taken in all such cases to ensure adequate immunological prophylaxis before hand

**Clinical Manifestations** Tetanus may occur in a localized form but more frequently the neuromuscular disturbance is generalized Local tetanus is seen chiefly in persons who develop symptoms despite the prophylactic administration of antitoxin and consists usually of persistent spasm in muscle groups near the site where the injury or wound was incurred The spasm may last in diminishing intensity for several weeks In rare cases of head injury a cephalic type of local tetanus has been described with

bizarre combinations of motor phenomena depending on the involvement of one or more cranial nerves

More typically the onset of tetanus begins with an increase in tone of various muscle groups often accompanied by restlessness irritability and difficulty in swallowing. Spasm of the masseter muscles which interferes with opening the jaws (trismus) is the most common initial symptom and its recognition should always suggest the possibility of tetanus to the physician. As the disease progresses stiffness and rigidity of the neck back abdomen and extremities become more pronounced and involvement of the facial muscles may cause a grotesque grinning expression classically referred to as *risus sardonius*. Tonic spasms usually ensue in which the teeth are tightly clenched the neck and back are arched (*opisthotonos*) the abdomen is taut and the extremities are rigidly extended. These spasms can be precipitated by the very slightest stimuli such as noise a draft of cold air jarring of the patient's bed sudden illumination of the room and so on. In severe cases they recur frequently and apparently develop spontaneously. Although duration of the individual tetanic episodes is ordinarily quite short their persistence is sometimes long enough to interfere seriously with the mechanics of respiration thus leading to anoxia and cyanosis and even to sudden death. However the cause of death is usually less readily apparent and is generally attributed to exhaustion. Throughout the disease the sensorium remains clear and therefore unfortunately the patient may be altogether unconscious of the severe pain which invariably accompanies each tetanic spasm. As a rule there is some degree of fever with temperatures exceeding 103° F in occasional cases as well as elevation of the pulse and respiratory rates. In patients who recover the signs and symptoms abate gradually after reaching their maximal intensity.

It should be noted that many variations in symptomatology may be observed especially during onset of the disease. By way of example the following initial manifestations have been described: fever and chilliness headache stiffness of gait abdominal pain caused by muscular spasm difficulty in swallowing pain in the neck and back and biting of the tongue.

**Laboratory Findings.** There are no laboratory procedures which are helpful in the specific diagnosis or management of tetanus. It has been suggested that electromyograms may aid in distinguishing the in-

cipient disease from other disorders of neuromuscular function but from the practical standpoint they are of little value. The electroencephalogram shows no abnormal changes even in fully developed cases thus indicating that the tetanic spasms are probably not cortical in origin.

Bacteriological examination as a means of diagnosis not only is almost worthless but also may be dangerously misleading. To isolate and accurately identify *Cl. tetani* from a wound requires a minimum of two or three days and the microorganism can not be recovered in a considerable proportion of cases. Moreover although *Cl. tetani* characteristically shows a terminal spore other terminally spored nonpathogenic anaerobes exist and may be present as incidental contaminants. The direct microscopic examination of wound material from a suspected case of tetanus should therefore be undertaken only by an expert. It is also important to point out that *Cl. tetani* may be found among the bacterial flora of many surface infections without evidence of harm to the patient. Consequently the chance discovery of *Cl. tetani* on routine bacteriological study does not imply that the disease will necessarily follow.

**Differential Diagnosis.** Once tetanus has developed the diagnosis is usually regrettably simple but in the early stages it may be confused with several other disorders. Local infections in the mouth may cause trismus especially when molar teeth are involved. The diagnosis in such cases ordinarily is obvious but the possibility of tetanus originating from such foci should always be borne in mind. Meningitis and encephalitis must also be differentiated at times although it is rarely possible for the alert physician to be seriously misled. Trismus and muscular spasms occur in certain cases of encephalitis but characteristically the sensorium is clouded and other neurological signs exist. In tetany the typical carpopedal spasm and absence of trismus should suffice to indicate the correct diagnosis. The writer has observed a case of hysterical trismus following a lacerated wound in a person familiar with the natural history of tetanus.

**Prognosis.** In severe cases of generalized tetanus the outlook is grave and the mortality rate still approximates 50 per cent despite recent advances in therapy. The unfavorable features to be stressed are a short incubation period and the rapid progression of symptoms after onset. Patients with an incubation period exceeding ten days generally have a more benign course.

and recover more frequently. The disease also is apt to be less dangerous and severe in cases with no evident focus of infection and in persons who develop tetanus even though antitoxin has been given prophylactically.

**Treatment** The treatment of tetanus varies widely according to the severity of the disease and the needs of the individual patient. In general, however, therapy is designed to prevent further elaboration and absorption of toxin to control tetanic spasms and to provide supportive measures which will maintain respiration, nutrition and fluid balance.

The usual dose of antitoxin in adults is 200 000 units intravenously to be given only after a preliminary test to determine whether the patient is hypersensitive to horse serum. If sensitivity is found to exist, desensitization by the standard method will have to be carried out before the total dose of antitoxin is administered. This amount of antitoxin should suffice to neutralize any preformed toxin which has not been absorbed as well as toxin liberated subsequently at the focus of infection; it will not affect toxin which already has been bound by nervous tissue. Local injections of antitoxin around the site of the wound or injury totaling 10 000 to 20 000 units may also be made although their efficacy is doubtful. The intrathecal use of antitoxin is not recommended.

Prompt surgical attention to the wounded or injured tissues is essential with special reference to careful debridement and the removal of foreign bodies. However, it is important not to undertake these procedures until antitoxin has been given in order that any toxin which is released by manipulation may be neutralized before it reaches the central nervous system. Penicillin should also be given since it has been shown to eliminate *C. tetani* rapidly in most but not all cases; it also aids in controlling secondary wound infections and serves as a prophylactic agent against the otherwise common complication of pneumonia. In most instances 300 000 to 400 000 units of a procaine penicillin preparation given every twelve hours will be adequate but in some cases larger amounts of penicillin and the additional use of other antimicrobial drugs with broader antibacterial spectrums may be required.

**Management of Muscular Spasm** The management of muscular spasms is of vital importance and may be extremely difficult especially if the patient is suffering from severe generalized tetanus. Treatment must

be suited to the individual case but it is essential that continuous nursing care be provided and that a physician always be in immediate attendance. Since therapy will not actually shorten the illness even though the course is greatly modified it must be continued until muscular spasms and rigidity have largely disappeared. The common procedure is to combine the use of sedatives in heavy dosage with a muscle relaxant drug. In order to administer these agents as well as to provide means for the intravenous administration of fluids, electrolytes and nutrients it is advisable to place at least one indwelling needle near the wrist or ankle. Two such needles are better for plugging may occur or it may be necessary to infuse immiscible drugs simultaneously, e.g. d-tubocurarine and thiopental sodium (Pentothal). Furthermore, the dosage of two drugs used concurrently by this route can be more accurately controlled if they are given separately. Sedation sufficient to cause loss of consciousness is usually required and thiopental sodium has generally been recommended as the drug of choice. A 2.5 per cent solution is given by vein in doses which can only be determined by the response of the patient. The objective is to cause relief of pain and spasm without dangerous depression of respiration. Since treatment must often be continued for a number of days it is important to bear in mind that thiopental sodium has a cumulative action when administered repeatedly. In many cases phenobarbital sodium and paraldehyde intramuscularly will be helpful adjuncts. Tribromoethanol (Avertin) given rectally has been used but is not recommended. Chloral hydrate also per rectum has been employed with satisfactory results in some patients but its irritative properties sharply limit the length of time it can be used by this route.

For muscle relaxation a number of drugs are available but the literature is conflicting as regards their relative efficacy and the extent to which they should be employed. Curare and curare-like compounds have been most frequently used and probably represent the agents of choice if they are intelligently and carefully administered. Their pharmacological effects are considered to result from a direct competition with acetylcholine which leads to a depression of excitatory action at the motor end plate. Thus they differ markedly from drugs like mephenesin (Myanesin, Tolserol) which causes central depression of reflex activity and from compounds producing

persistent end plate depolarization by an acetylcholine like effect e.g. succinylcholine *D* tubocurarine chloride may be used as a repository preparation in oil and wax containing 30 mg per ml. The usual initial dose is 0.5 ml and later doses may be increased to 1.0 ml or more depending on the response of the patient. The rapidity of absorption from this depot form of curare is usually slow but may vary considerably. Consequently it may be found advisable to employ *d* tubocurarine chloride intravenously in an isotonic aqueous solution containing 3 mg per ml the initial dose generally being 3 mg for each 40 pounds of body weight. Larger amounts may be required according to the needs of the patient but the drug must always be given under constant supervision with the knowledge that successive doses tend to show a cumulative type of effect. The respiratory difficulty sometimes observed in patients receiving curare which results not from muscular paralysis but from bronchiolar spasm may be controlled by antihistaminic therapy. Another compound similar to curare in its action is tri (diethylaminoethoxy) benzene triethylthiodide (*Flaxedil*) which is claimed not to cause histamine like side reactions. The initial intravenous dose of *Flaxedil* is approximately 1 mg per kg of body weight. If the use of a curariform compound is not desired *mephnesin* may be given by vein in a 2 per cent solution. This drug must be diluted in isotonic glucose or saline since it readily provokes phlebitis it is also a hemolytic agent and hemoglobinuria has been seen following its use. *Mephnesin* is short acting and its dosage varies considerably from 1 to 6 gm being given over a one hour period. Succinylcholine, decamethonium and muscle relaxants of a similar type may also be employed but information concerning their use is insufficient to warrant recommending them as the drugs of choice.

It has been reported that chlorpromazine may be used to advantage in combination with barbiturates and muscle relaxing agents and that it prolongs the sedative and anticonvulsant action of these drugs without causing circulatory or respiratory depression as well as relieving apprehension. The best results apparently are obtained by intravenous administration.

Cortisone is of dubious value in the treatment of tetanus.

**Tracheotomy.** In all cases it is essential that provision be made for the immediate treatment of respiratory arrest and for the

maintenance of the patient's airway. Cumulative experience has indicated more and more that early tracheotomy should be performed in severe cases in order to circumvent the problem created by laryngeal spasm and to permit the easy use of tracheal suction for removing secretions. In addition tracheotomy will permit emergency oxygen therapy under intermittent positive pressure using the apparatus described by Harris and her associates. In some cases a mechanical respirator will be necessary.

Tetanic spasms are usually accompanied by profuse sweating and throughout the illness proper attention must be devoted to maintenance of the fluid and electrolyte balance and the nutrition of the patient. In severe cases under heavy sedation a nasogastric tube may be inserted for feeding by this route but it should be borne in mind that the use of muscle relaxant drugs also may cause relaxation of the cardiac sphincter with a tendency to regurgitation. Intravenous fluids containing glucose, balanced electrolytes and amino acids should be used as in any situation in which prolonged parenteral alimentation is required and periodic chemical examinations of the blood should be carried out to aid in guiding this phase of therapy.

Following recovery from tetanus the patient should always be actively immunized in order to prevent possible recurrence of infection from retained spores of *C. tetani*. There is no evidence that the disease itself confers subsequent immunity and second attacks have been described.

**Prevention.** The greatest single advance in the management of tetanus has been the development of methods for specific immunization against the toxin. When such methods are properly employed the disease is almost entirely preventable. It should be emphasized that antimicrobial drugs are not effective preventive agents and must never be used alone in tetanus prophylaxis.

Temporary immunity may be passively transferred by the subcutaneous injection of tetanus antitoxin the usual dose being 1500 units regardless of the age or weight of the patient. The antitoxin is actually standardized immune horse serum and can cause severe or even fatal anaphylactic reactions in persons previously sensitized or allergic to horse protein. Whenever possible therefore a history of earlier immunizing procedures and allergic symptoms should be carefully sought and even when this is negative injection must be preceded by an intradermal test with 0.01 ml of the anti-

serum Positive reactions to the test indicating hypersensitivity are of the immediate wheal and flare type occurring within less than fifteen minutes

The great value of antitoxin was first conclusively demonstrated during World War I and today it is still the only reliable means of preventing tetanus in persons who have not been actively immunized. However it has many shortcomings, most but not all of which result from the fact that it is a foreign protein. In addition to the hazards of its use in patients who are already allergic, a prophylactic dose of antitoxin may itself engender sensitivity to horse serum, thus creating a difficult problem if readministration becomes necessary, as well as a dangerous situation if other types of therapeutic horse antisera should be given subsequently. The writer has seen sudden anaphylactic death in a patient who incautiously was given gas gangrene antitoxin ten days following the prophylactic use of tetanus antitoxin. Besides reactions of this sort, antitoxin may cause either general or local serum disease of varying severity; it is also responsible in rare instances for a peculiar form of peripheral neuritis, predominantly involving the brachial plexus, the mechanism of which, although not well understood, presumably has an immunological basis. Passive immunization against tetanus also has other drawbacks, the most notable being that antitoxin obviously cannot be given after every traumatic event while the physician has no way of predetermining when its use will be essential.

*Tetanus prophylaxis is more readily and more safely achieved by active immunization with toxoid, which is available in two forms: fluid and alum-precipitated, the latter type being more slowly absorbed and providing a longer antigenic stimulus.* Experiment has revealed in man that one injection of either toxoid causes little or no antitoxin to appear in the blood. A second injection three to four weeks later usually results in the development of measurable antitoxin equal to or exceeding 0.1 standard unit per milliliter of serum, which is generally accepted as the protective level. A third injection after another three to six months stimulates an even more marked antibody response, and thereafter adequate amounts of circulating antitoxin can be readily maintained by booster doses at intervals of three to five years. At the time any injury is sustained that warrants tetanus prophylaxis, the person who has com-

pleted the basic course of immunization and has continued to receive stimulating injections is merely given another dose of toxoid; antitoxin is not administered. Immunization in this manner was extraordinarily successful in preventing tetanus among the armed forces of the United States during World War II: only 6 cases occurring in the Army and 2 in the Navy among personnel who had received the basic course of injections. All these cases had short incubation periods and hence probably represented massive infections; in addition, it is possible that some of them had low serum titers of antitoxin since not all persons are good antibody formers.

It is generally recommended that children or adults be immunized by giving three subcutaneous injections of 0.5 ml fluid toxoid at intervals of three to four weeks, or two injections of 0.5 ml alum-precipitated toxoid four to six weeks apart. Another injection of 0.5 ml of either toxoid should be given six months to one year later. Thereafter stimulating doses of 0.5 ml should be administered every four years. In the event that prophylaxis becomes desirable, a stimulating injection of 0.5 ml of fluid toxoid is given, since this induces a more rapid rise in antitoxin than does alum-precipitated toxoid. If a previously immunized patient has not received toxoid for more than five years, it is advisable to give both antitoxin (1500 units) and fluid toxoid (0.5 ml). Separate syringes must be used since mixture in the same syringe will result in partial or complete neutralization. There is experimental evidence that the combined use of antitoxin and toxoid causes an initial sharp rise in the blood level of antitoxin, provided by the passively transferred antibody which is overlapped by a secondary sustained elevation resulting from the antigenic stimulus of the toxoid. In patients who are seriously injured with shock, compound fractures or large massively contaminated wounds, some authorities advocate that both antitoxin and toxoid be used regardless of the status of antecedent immunization.

Proper surgical care is also essential in the prevention of tetanus. In all types of trauma, whether suffered in military or civilian life, the well-known principles of prompt treatment, adequate débridement of wounds, and the control of shock and secondary infection are of paramount importance.

## Salmonella Infections

## TYPHOID FEVER

**Definition** Typhoid fever is an acute illness lasting several weeks caused by *Salmonella typhosa* and characterized by sustained fever with headache and apathy, cough, splenomegaly, a sparse maculopapular eruption and leukopenia.

**Etiology** *Salmonella typhosa* is a motile gram negative bacillus which grows readily on simple infusion media. Formerly called *Eberthella typhosa* it is now classified in the *Salmonella* group by most authorities because of similarities in biochemical properties, antigenicity and pathogenicity. Unlike most salmonellas it fails to produce gas during fermentation of sugars. Final identification is made by agglutination with specific serum.

The principal antigenic components of the typhoid bacillus are the flagellar or H antigen which is heat labile and the O or somatic antigen which is heat stable. Virulent forms have another antigen located on the surface of the cell called the Vi antigen.

At least twenty strains of *S. typhosa* have been differentiated on the basis of susceptibility to lysis by bacteriophages. This procedure has been helpful in studies of the epidemiology of typhoid but is not useful in clinical practice since there is no significant variation in the disease produced by different strains.

**Epidemiology** *Salmonella typhosa* is a parasite of man and does not cause disease of other animals in nature. The organisms are excreted in the urine and feces by patients with typhoid fever usually disappearing from the urine during the acute illness but sometimes persisting in the stools dur-

ing convalescence. Occasional patients become permanent carriers continuing to excrete bacilli in the stools for years after recovery from the disease. Urinary carriers are rare except when there is coexistent disease of the urinary tract; for example patients with schistosomiasis become urinary typhoid carriers rather commonly. The bacilli do not multiply significantly outside the human body but may survive for weeks or months under natural conditions. The danger from excreta of typhoid patients is well recognized and simple precautions are effective in preventing infection of other persons. Much more difficult to control is spread of the disease by apparently healthy carriers who are responsible for its perpetuation.

Infection of man invariably occurs by ingestion of fecally contaminated material. Direct contamination of uncooked foods such as salads and raw milk by the soiled hands of a carrier has been the cause of many outbreaks while epidemics have occurred from sewage contamination of water or shellfish. Flies may transmit the bacilli from feces to food. Modern municipal methods of water supply and sewage disposal together with pasteurization of milk have almost eliminated large epidemics of typhoid fever. As a result of these measures supplemented by improved sanitation in rural areas and active immunization, the prevalence of typhoid fever has declined greatly in the United States since 1900. Although formerly occurring in huge summer epidemics, the disease is now seen sporadically throughout the year. Cases appear singly or in small groups and most of them are traceable to contamination of food by typhoid carriers.

**Pathogenesis** Typhoid bacilli enter the body through the mouth. It has been suggested that the organisms may lodge in the tonsils or pharynx and invade the interior of the body from there. It seems more probable however that they pass through the stomach into the small intestine, penetrate the lymphoid tissue in its wall and are transported to the mesenteric lymph nodes. Multiplying in these locations the organisms then pass probably via the thoracic duct into the blood stream where they can regularly be demonstrated in cultures taken during the first week or ten days of illness. The bacilli localize in lymph nodes, spleen, lungs, bone marrow and liver. Since bile is a good culture medium for *S. typhosa*, luxuriant growth takes place in the biliary tract; this provides a continuous discharge of organisms into the small intestine, and

contributes to the heavy involvement of the Peyer's patches which occurs during the second and third weeks of the disease. The infection of the biliary tract also accounts for the positive stool cultures usually found at this stage. Cultural studies on persons who die during the second or third week of typhoid fever have shown that the greatest concentration of the bacilli is in the biliary tract and duodenum with progressive diminution in the number of organisms in the remainder of the small bowel and the colon.

Antibodies for the typhoid bacillus generally appear in the blood during the second week of the disease and at about the same time bacteremia usually ceases. There is no slackening however in the clinical manifestations. The role played by antibodies in recovery is uncertain as is the reason for gradual regression of the infection. There is some evidence however that typhoid bacilli can grow within cells particularly in plasma cells where they may be protected until the death of the sheltering host cells exposes them to the combined assault of antibodies and phagocytes. Such a process might explain the slow defervescence of the disease.

Second attacks of typhoid fever have been observed but as a general rule one attack confers lifelong immunity.

**Morbid Anatomy** In nearly all tissues of the body there is proliferation of large mononuclear cells derived from reticulo endothelial tissue. Lymphoid hyperplasia is notable everywhere but especially in the Peyer's patches of the ileum, the mesenteric lymph nodes and the spleen. The Peyer's patches may undergo necrosis leading to intestinal perforation or to hemorrhage. The liver is usually enlarged and local areas of necrosis can be seen microscopically. There may be a diffuse patchy pneumonitis.

**Symptoms** The clinical manifestations of typhoid fever are subject to great variation in character and intensity. The disease may take the form of a mild illness lasting only a week or two or it may last six to eight weeks. Occasionally it is a fulminating process which overwhelms the patient within a period of ten days. The description to follow will pertain to cases of average severity lasting four to five weeks.

The incubation period is ten to twelve days. Abrupt onset is unusual more often there is gradual development of malaise, headache and feverishness causing the patient to take to his bed about the third or fourth day. The fever is remittent in type, tending to be higher each day. During the

first ten days headache is likely to be the most prominent symptom accompanied by general malaise and a nonproductive cough. Anorexia is the rule occasionally with nausea and vomiting. Constipation is common during the first two weeks of illness and there is often generalized abdominal discomfort and distention. Epistaxis is an early symptom in about one fifth of all cases. By the third week the fever is generally high varying from 102° to 104° or 105° F each day. There are periods of profuse sweats and occasional chills associated with the temperature variations. Administration of an antipyretic drug is likely to result in a precipitous fall in temperature followed in a few hours by a chill and rapid return to the previous level. There may be delirium at the peaks of fever. The sensorium is dulled, the patient often has a blank staring expression and may pick aimlessly at the bedclothes. At this stage diarrhea may supervene and several watery grayish or greenish stools may be passed each day.

Once the fever reaches a plateau it is sustained for a week or two then gradually begins to lessen. Each day the remission is greater and the elevation a little less, normal temperature being attained after about thirty days of illness.

**Physical Signs** Physical findings vary according to the stage of the disease. In the first week aside from feverishness and perhaps slight abdominal distention there are no helpful physical signs. During the second week the spleen becomes palpable in about three fourths of all cases. It is soft not greatly enlarged and may not be felt if palpation is carried out too firmly. The rash appears during the second and third week. It can be seen in about 90 per cent of white patients but is difficult to detect in the Negro. It consists of crops of round slightly elevated rose spots 2 to 8 mm in diameter which blanch under tension and persist two to five days. The lesions are seldom numerous, often less than a dozen can be seen at a time. They are found principally on the trunk, especially on the upper abdomen and lower chest; rarely they are found on the face and extremities. Examination of the lungs may reveal scattered moist rales, evidence of the bronchitis which is commonly present in typhoid fever. During the first two weeks of illness the pulse rate may be comparatively slow in relation to the fever, e.g. 85 per minute at a temperature of 104° F, but subsequently the pulse rate is usually proportional to the fever. At the height of the illness abdominal

distention may be severe and there may be moderate generalized abdominal tenderness most pronounced on the right side. All these signs subside as the fever diminishes and by the time the temperature has returned to normal the rash, splenomegaly, abdominal distention and bronchitis have usually also disappeared. Convalescence is slow; the patient is seldom able to resume former activity within a month after the fever subsides.

Older descriptions of typhoid fever based upon the clinical picture seen around 1900 stressed the remarkable wasting which occurred as well as changes in the mouth and tongue, sordes on the lips and teeth and parotitis. With good nursing care, administration of adequate fluids and nutriment these developments are now rarely encountered and will not be described in detail.

**Laboratory Findings.** During the course of the illness a normochromic anemia develops. This may be aggravated by extensive bleeding into the bowel. As a rule the leukocyte count is normal during the first two weeks of illness; in the third and fourth weeks there is usually a neutrophilic leukopenia, the total count ranging from 3000 to 6000 cells per cu mm. Albuminuria of moderate degree is common when the fever is high. The feces usually give a positive reaction for occult blood during the third and fourth weeks of the illness and some times they contain gross blood.

**Isolation of *S. typhosa* from the Blood.** It is possible to isolate *S. typhosa* from the blood in nearly all cases during the first week of illness but with diminishing frequency thereafter. Blood culture is rarely positive after the third or fourth week unless the patient remains acutely febrile. The organisms can often be cultivated from bone marrow however until the fourth or fifth week of illness. Typhoid bacilli do not appear in the feces until the second or third week but by the fourth week stool culture is positive in approximately 85 per cent of cases. The frequency of positive cultures declines rapidly thereafter and by the sixth or seventh week is less than 5 per cent. In approximately 2 to 3 per cent of cases the organisms continue to be excreted in the feces long after clinical recovery, i.e. the patient becomes a typhoid carrier. This state may continue for as long as twenty or thirty years or may cease spontaneously at any time. The urine culture reveals *S. typhosa* during the third or fourth week in about 25 per cent of cases but persistent excretion of the bacilli is rare.

**Serological Tests.** Demonstration of de-

velopment of H and O agglutinins (Widal reaction) during the course of an illness is strong evidence in support of the diagnosis of typhoid. However two sources of misinterpretation should be recognized. Persons inoculated with typhoid vaccine within the previous six to twelve months may have agglutinins. Moreover persons who have previously had the disease or been vaccinated may exhibit an anamnestic reaction with reappearance of typhoid antibodies during some other febrile illness, especially typhus fever or brucellosis. Recent vaccination can usually be ascertained from the history. The anamnestic response is characterized by early rise and fall in titer and by the fact that serological reactions for the responsible disease rise to even higher titers and persist longer than the typhoid antibodies. It is useful to test for both O and H antibodies in the Widal reaction since infections with serologically related salmonella organisms may serve as antigenic stimulus for one or the other of these. The H titer usually is higher than the O. No arbitrary level can be given as diagnostic; occasional patients never have antibody titers higher than 1:40 or 1:80. Demonstration of a rising titer is more significant than any single level although titers of 1:160 or greater, especially for antibodies to the O antigen, are strongly suggestive of active infection. Tests for Vi antibodies are technically more difficult but a positive result is especially significant because typhoid vaccination does not usually cause development of Vi antibodies.

**Complications.** The most frequent serious complication is hemorrhage from the small bowel which results from erosion of blood vessels in the ulcerated Peyer's patches. As already noted, bleeding sufficient to give a positive test for occult blood in the feces occurs in nearly every case of typhoid fever during the third and fourth week. Gross blood is present in 10 to 20 per cent of all cases. Profuse bleeding is sometimes fatal. Serious blood loss is evidenced by pallor, shortness of breath, tachycardia and fall in blood pressure. In some instances there is also an abrupt fall in body temperature. Perforation of the intestine is less frequent (about 2 per cent of cases) but is an even more serious complication, often resulting in death. Gross intestinal hemorrhage some times precedes perforation. The clinical signs of perforation are often obscured by pre-existing abdominal distention, pain and tenderness. Usually, however, sudden intensification of pain occurs in the right lower abdomen with localized tenderness.

and diminished or absent peristalsis Free air within the peritoneal cavity may be demonstrable on a roentgenogram The pulse rate often increases and a rise in leukocyte count is a helpful diagnostic sign *Pneumonia* may occur as an extension of the bronchitis which usually accompanies typhoid fever but occasionally it is caused by pneumococcus or some other microorganism *Cholecystitis* occurs in 2 to 3 per cent of patients and is characterized by pain and tenderness in the right upper quadrant *Cholelithiasis* may develop as a late sequel *Periostitis* occasionally occurs during or after the febrile period It is usually situated near the end of a long bone or in one of the vertebrae The lesion tends to flare up and subside at irregular intervals over long periods of time Typhoid *pyonephrosis* has been described *Thrombophlebitis* is uncommon *Meningitis* is rare *Arthritis* is also a rare complication the large joints being the ones affected *Abortion* or *premature delivery* almost always occurs in pregnant women

**Relapse** Relapse occurs during convalescence in about 10 per cent of cases This may amount to only a few days of fever or there may be a reappearance of all manifestations including bacteremia and "rose spots" The course is usually short however and the clinical illness milder than the initial attack

**Diagnosis** During the first week of illness the diagnosis can be established by blood culture The appearance of rose spots and enlarged spleen during the second week is suggestive and at this time a rising titer of antibodies is usually demonstrable During the third and fourth weeks the causative organisms can nearly always be isolated from the feces Culture of bone marrow may be resorted to at any time during the first four or five weeks

**Differential Diagnosis** Because of the insidious onset with cough typhoid fever can be confused with *primary atypical pneumonia* Demonstration of pulmonary consolidation within the first week and development of cold agglutinins point to the correct diagnosis *Murine typhus fever* may be difficult to distinguish from typhoid Typhus fever is more likely to have a sudden onset with chills and a more profuse skin eruption Laboratory tests include a positive Weil-Felix reaction and positive complement fixation reaction with typhus rickettsiae Clinical improvement with tetracycline would favor typhus fever In *tularemia* there may be a history of handling wild rodents or of tick bite and an ulcer

with regional lymphadenopathy may be found Clinical improvement with streptomycin or tetracycline would suggest this diagnosis and development of agglutinins for *Pasteurella tularensis* would confirm it In *Rocky Mountain spotted fever* the onset is abrupt there may be a leukocytosis and the hemorrhagic eruption is usually heaviest on the wrists and ankles The Weil-Felix reaction and complement fixation test are positive after ten days This illness also responds dramatically to therapy with one of the tetracyclines *Pulmonary tuberculosis* can usually be differentiated by roentgenographic studies but the presence of *miliary tuberculosis* is more difficult to exclude since lesions are not always demonstrable on the roentgenogram In such instances the diagnosis may be established by the appearance of choroidal tubercles the finding of tubercles in sternal marrow or the development of meningitis *Hodgkin's disease* localized chiefly in the abdomen may resemble typhoid fever but can be differentiated by negative bacteriological and serological tests for typhoid and eventual development of characteristic lesions in the mediastinal or superficial lymph nodes *Brucellosis* may be clinically similar but in cases which resemble typhoid antibodies against brucella or the microorganisms themselves should be demonstrable in the blood *Malaria* may have an onset similar to that of typhoid but the typical relapsing course usually becomes established after a few days and the plasmodia can be demonstrated in the blood smear The *paratyphoid fevers* simulate typhoid fever in all respects but are usually milder They can be differentiated only by serological and bacteriological methods

**Prognosis** Before the introduction of chloramphenicol the overall case fatality rate of typhoid fever was 8 to 10 per cent The prognosis is especially grave in cases with profuse hemorrhage or perforation It appears probable that with chloramphenicol therapy the fatality rate in typhoid fever can be reduced to less than 1 or 2 per cent

**Treatment** Attendants should be immunized against the disease They should wear gowns and should wash their hands with soap and water after contact with the patient or anything he may have touched Eating utensils should be boiled Bedding towels and so forth should be boiled The stools and urine can safely be disposed of in municipal sewage systems

Until 1948 there was no specific treatment for typhoid fever and patients with the disease had to go through a prolonged

severe febrile illness. Careful nursing, various supportive measures and maintenance of fluid balance and nutrition were of utmost importance. With the introduction of chloramphenicol the situation has been altered. This drug terminates the febrile period so quickly that the relative importance of nursing and general supportive measures has lessened.

It is advisable to administer 2 or 3 gm of chloramphenicol daily during the first few days until the temperature is normal. Thereafter a total daily dose of 1.0 to 1.5 gm is apparently adequate. The daily dose can be divided into two or four parts and given at twelve or six hour intervals. The pattern of response is remarkably uniform. During the first two days there is little or no apparent change in the clinical condition. Fever continues and the symptoms are not modified. Blood cultures reveal however that the bacteremia terminates within the first few hours after starting treatment. During the third day dramatic improvement usually takes place. The temperature subsides, the symptoms abate, the appetite improves and the patient enters the convalescent stage.

It has been shown that an even more dramatic clinical improvement can be obtained by giving an adrenal corticosteroid as an adjunct to chloramphenicol therapy. Cortisone in a dose of 200 mg daily for four or five days causes a rapid defervescence and lessening of the symptoms. It can be discontinued at the time chloramphenicol would be expected to have the infection controlled. So far as has been determined this use of cortisone has not been harmful to the patient.

Relapses have been encountered in patients treated with chloramphenicol for only seven to ten days but resumption of the chemotherapy brings about rapid improvement. Relapses can probably be prevented by continuing drug administration (in a dose of 1 gm daily) for three to four weeks. Complications such as hemorrhage or perforation of the bowel may also occur even though the patient is afebrile and otherwise asymptomatic after chloramphenicol treatment and indicate the need for prolonged rest and careful observation. Probably these complications can be reduced to a minimum by continuing chloramphenicol therapy for three to four weeks in all cases.

Should a large hemorrhage occur blood transfusions are indicated. The treatment recommended for perforation of the bowel formerly was surgical drainage but conservative treatment with tetracycline and

chloramphenicol is now probably preferable.

**Treatment of Carriers.** Persons known to be carriers should not be permitted to work as food handlers. The members of their households should be immunized against the disease. Chloramphenicol is not effective in eliminating the carrier state. Cholecystectomy will eradicate the carrier state in about 90 per cent of cases. Before resorting to surgery however a trial of penicillin therapy in large doses should be given, i.e. 10,000,000 units daily for 10 days. This occasionally succeeds in terminating the carrier state.

**Prophylaxis.** Immunization against typhoid fever is practicable and reasonably satisfactory. The vaccine usually used contains 1 billion heat killed organisms per ml. In some parts of the world paratyphoid A or B bacilli are also included. A course of immunization usually consists of three subcutaneous injections given at weekly intervals, the individual doses being 0.5, 1.0 and 1.0 ml. The injection often causes some local soreness and there may be fever during the succeeding six to twelve hours. The vaccine can be inoculated intracutaneously in doses of 0.1 ml. This method reduces the likelihood of systemic reaction but the local pain and tenderness are as uncomfortable as with subcutaneous injection of the larger quantities. Except with massive exposure the immunity conferred is reasonably satisfactory for six to twelve months and in many persons for considerably longer periods of time.

#### SALMONELLOSIS OTHER THAN TYPHOID FEVER

**Definition.** Salmonella infections are a group of acute illnesses caused by the numerous members of the genus *Salmonella*. The clinical picture may cover a spectrum ranging from severe enteric fever closely resembling typhoid to mild gastroenteritis.

**History.** The typhoid bacillus observed in tissue sections by Eberth in 1880 and isolated by Gaffky in

1884 was the first of a series of related organisms found to produce enteric infection in man. *Salmonella enteritidis* was isolated by Gaertner in 1888 and *S. typhimurium* shortly thereafter both from cases resulting from the ingestion of infected meat. *S. schottmuelleri* was obtained by Gwyn from the blood of a patient with paratyphoid fever in 1898. *S. paratyphi* from contaminated water by Paladino-Blandino in 1903 and *S. hirschfeldii* by Hirschfeld from cases of paratyphoid in Mesopotamia during the First World War among troops who had been immunized with TAB vaccine. *Salmonella choleraesuis* isolated in 1885 by Salmon and Smith from swine and from cases of enteric fever in man by Longcope in 1902 was originally thought to be the cause of hog cholera but subsequent work has shown that it is only a frequent secondary invader in a disease caused by a virus. The work of a large number of medical and veterinary bacteriologists has led to our present knowledge of this ubiquitous and important group of enteric organisms which now comprises over 150 species.

**Etiology** The salmonellas are gram negative motile bacilli which may be distinguished from bacilli of the coli aerogenes group by their inability to ferment lactose and by their capacity for growth in the presence of certain compounds which inhibit the latter organisms. These two characteristics form the basis for the methods using enrichment and differential media for their isolation from feces. As a group the salmonellas do not produce indol or liquefy gelatin but do not ferment sucrose, lactose or salicin but produce acid and gas when grown in the presence of glucose, mannitol and maltose with two exceptions—*S. typhosa* and *S. pullorum* which produce acid but no gas. Identification of individual strains is usually made on the basis of biochemical activities and serological reactions in properly prepared antisera.

The modern serological classification of the salmonellas is based on studies of their antigenic structure by Kauffmann and White. They may be divided into seven groups on the basis of their O (somatic or heat stable) antigens and within these groups the individual types or species may be identified by their H (flagellar or heat labile) antigens. Few laboratories are equipped for more than isolation of salmonellas and tentative identification of one of the common types. Correct identification is important in tracing the epidemiology of these infections consequently many laboratories now forward the strains which they isolate to one of the Salmonella Centers for final identification.\*

**Epidemiology** The salmonellas are natural pathogens for a wide variety of ani-

mals and birds. In general they may be divided into three classes: (1) those species found only in man; (2) those usually found in animals or birds but capable of causing disease in man; and (3) those found only in animals or birds. The first class is small including *S. typhosa*, *S. paratyphosa*, *S. schottmuelleri* and *S. hirschfeldii*—in other words the typhoid and paratyphoid A, B and C bacilli. All these organisms may cause enteric fever in general with some what diminishing frequency and severity as one moves down the list. In contrast the frequency with which sepsis with focal complications or severe gastroenteritis characterizes the infection increases as one ascends the list. The second class is the largest and is constantly growing. The third is shrinking with more thorough bacteriological studies of sporadic cases and outbreaks of food poisoning. Organisms of the second class rarely cause enteric fever but most often gastroenteritis or septicemia.

Human infections with salmonellas are occasionally acquired by contact with infected animals but usually by ingestion of contaminated water or food. Contamination of water and food may be caused by the excreta of animals such as rodents by flies by human beings who are sick or who are carriers or by infection in animals which are used as food. Meat, milk and eggs are the foods most frequently involved in transmission since the organisms may multiply in them before ingestion. This rapid growth results in a large dose of bacteria and thus increases the likelihood of infection with *Salmonella* types of low pathogenicity for man.

Important factors in spread are the relative resistance of the organisms to physical and chemical agents, their ability to multiply outside the bodies of their hosts, their widespread distribution in rodents, domestic animals and fowls and the frequency of human carriers. Approximately 3 per cent of typhoid patients become permanent carriers after the illness. Although the percentage of permanent carriers is lower after paratyphoid infection, a considerable number may carry the organisms for weeks or months and with the less pathogenic types inapparent infections occur frequently.

**Pathogenesis** Much of our knowledge of the pathogenesis of enteric fever is derived from studies on typhoid fever by Goodpasture and Adams based on correlation of postmortem findings with experimental work in the chick embryo.

The pathogenesis of infection with *Salmonella typhosa* is described in the im-

\* Salmonella Typing Center, Agricultural Experiment Station, University of Kentucky, Lexington, Kentucky, or Salmonella Center, Beth Israel Hospital, New York City.

mediately preceding section on Typhoid Fever. Presumably the general features of infection with other salmonellas are similar but permanent localization within the biliary system is much less common as is deep ulceration of the lymphoid tissue of the bowel. Relapses and recrudescences appear to be due to reinvasion of the blood from secondary foci of infection.

**Immunity.** The degree to which an attack of infection with one *Salmonella* species confers protection against subsequent attacks with the homologous species or others of the same group is largely unknown. Presumably the degree of immunity conferred by the disease will depend upon the intensity of the antigenic response evoked by the attack, the interval before reexposure and the dose of infecting organisms. This is borne out by experimental feeding of volunteers and by studies on actively immunized persons which indicate that the protection conferred by prophylactic vaccination is relative not absolute.

**Morbid Anatomy.** The pathological lesions found in these infections are not particularly specific. Death seldom occurs except in severe enteric fever or in the septic cases. The findings in the former are those of typhoid fever although the involvement of Peyer's patches is less prominent and ulceration much less frequent. In the septicemic forms of infection intestinal lesions are usually absent and the findings are those of any acute generalized infection—acute splenic tumor, focal necrosis of the liver, cloudy swelling of the kidneys, widespread petechial hemorrhages and occasional purulent foci in which the exudate consists of mixed polymorphonuclear lymphocytes, plasma cells and macrophages.

**Pathological Physiology and Chemistry.** Like other gram negative organisms of the enteric groups the O or somatic antigens of the *Salmonella* are polysaccharide-lipid protein complexes. These antigens presumably are the heat stable endotoxins released as the result of autolysis and destruction of organisms in the body which give rise to many of the manifestations of the infection. This statement is based on the result of clinical and experimental studies with purified endotoxins. Their intravenous injection into human beings in minute amounts is followed after a latent period of thirty minutes to an hour by chill, fever, headache, nausea, malaise and leukopenia. Recent studies by Wood and others suggest that the fever actually is caused by endogenous pyrogen released from leukocytes dam-

aged by the action of endotoxin. Antibodies against the O antigen develop after a week or two for the organisms from which the endotoxin was derived and the patient shows a steady increase in tolerance requiring constantly increasing doses to elicit the effect on each succeeding injection. This phenomenon which is characteristic of the response to intravenous typhoid vaccine is not specific; that is the tolerance is increased for endotoxins derived from any of the organisms of the enteric group and appears to be related to hyperplasia of the reticuloendothelial system.

**Incidence.** The incidence of salmonella infections bears a general relation to the degree of sanitation. However in the United States despite the low incidence of typhoid fever in all but certain rural areas other salmonella infections occur with greater frequency. The New York Salmonella Center collected 2916 cultures of *Salmonella* excluding *S. typhosa* in the period from 1939 to 1945 comprising 53 types in 7 groups with the following distribution: A (1 type) 0.7 per cent, B (11 types) 32.6 per cent, C<sub>1</sub> (11 types) 40 per cent, C (7 types) 11 per cent, D (5 types) 5 per cent, E (8 types) 9 per cent, F (10 types) 1.7 per cent. The species most commonly isolated were the following: the figures indicating the number of isolations: *S. typhimurium* 795, *S. schottmuelleri* 148, *S. derby* 71, *C. S. oranienburg* 709, *S. choleraesuis* 144, *S. montevideo* 134, *C. S. newport* 270, *D. S. panama* 95, *S. enteritidis* 44, *E. S. anatum* 181.

**Symptoms.** Salmonellas cause three major syndromes in man: enteric fever, septicemia and acute gastroenteritis. Although any of the pathogenic salmonellas may produce any of these three types of disease, each syndrome tends to be associated with certain species. The clinical pictures of these three syndromes are not completely distinct and many cases are seen in which the picture of one syndrome shades into the other.

Enteric fever caused by *S. paratyphosa*, *S. schottmuelleri* or *S. hirschfeldii* and occasionally by other members of the group closely resembles typhoid fever but tends to be shorter in duration and milder and to have fewer complications although it can be a severe and serious disease. The incubation period is shorter (one to ten days), rose spots are less frequently seen than in typhoid, diarrhea is more common and there is considerably less ulceration of the small bowel so that hemorrhage and perforation although they may occur are

FIG 25 Clinical course of septic type of infection due to *S. choleraesuis* in a 21 year old primiparous woman who had had a spontaneous delivery during the disease and who acquired pneumonia and arthritis of the sacroiliac joint as focal complications. The baby appeared ill for the first week but recovered *S. choleraesuis* was isolated from its stools on the twentieth day of life (Goulder Kingsland and Janeway New England J Med 226 127 1942)

less often observed. Relapses are common and although the permanent carrier state occurs rarely as many as 20 per cent of patients may have positive stool cultures for several months after *S. schottmuelleri* infection. The differences between paratyphoid fever and typhoid fever are quantitative rather than qualitative and these two infections can be distinguished only by bacteriological methods.

The septicemic type of infection is seen most often when *S. choleraesuis* (*B. suis* *tifer*) is the infecting organism. This type of infection occurs sporadically and is usually seen in children or in adults debilitated by other diseases, surgical operations or malnutrition. The illness begins with an acute onset of high fever occasionally preceded by a chill. In a few cases the onset is more gradual. The bacteremia is uncomplicated by the development of focal lesions in about two thirds of these cases and the course is that of a typhoid like febrile disease with leukopenia and fever lasting one to three weeks. Tachycardia is much more common than bradycardia and although cough, coryza, headache, delirium, stupor, vomiting, constipation and diarrhea all may occur as in typhoid fever they are much less frequent symptoms. Intestinal hemorrhages and perforation have not been described.

Focal complications are more frequently observed than in typhoid and paratyphoid fever. Pulmonary lesions, particularly bronchopneumonia, have been noted in about

one third of the cases. Lobar pneumonia, pleural effusion, empyema and pericardial effusion have been observed. In some cases the organisms have been isolated from the sputum or from the lung at autopsy.

Bone and particularly joint lesions occur in about 20 per cent of cases according to Harvey. The lesion is usually a pyarthrosis with organisms present in the greenish fluid which accumulates in the joint space and with involvement of the adjacent bone. Any joint may be involved and the lesions frequently occur after the acute systemic infection has subsided.

Purulent meningitis, particularly in infants and children, bacterial endocarditis superimposed on damaged valves, pyelonephritis and abscesses in various parts of the body have all been described as complications of *S. choleraesuis* infection.

The characteristic laboratory findings are a mild anemia which progresses during the disease and leukopenia which may be followed by the development of leukocytosis when focal complications appear. Bacteremia occurs in a high percentage of cases and persists throughout most of the febrile course. The agglutination reaction becomes positive to a high titer in most cases. Positive urine cultures are frequently obtained but positive stool cultures are rare.

Acute gastroenteritis usually occurs in epidemics and may be caused by any of the salmonellas but *S. typhimurium*, *S. oranienburg* and *S. newport* are probably most often implicated in this country. It results

from the ingestion of heavily contaminated food and begins abruptly with fever, head ache, abdominal pains, nausea, vomiting and diarrhea after an incubation period of six to forty-eight hours. In a few cases in any outbreak, bacteremia may occur with high fever and chills or in children convulsions and drowsiness at onset, cough, pneumonitis, splenomegaly, muscle pains and weakness. The course is brief, usually lasting two to five days, and the mortality low. Generally there is leukopenia, although leukocytosis often occurs, particularly at the onset. The clinical picture in such outbreaks depends to a considerable extent on the dose and pathogenicity of the infecting species. In many instances when the dose is small or the infection due to organisms of low virulence for man such as *S. paratyphi* or *S. anatum*, gastroenteritis may be mild so that diarrhea, cramps and slight fever are the only manifestations of infection. In any outbreak a number of persons are found in whom positive stool cultures are obtained although they have no symptoms.

**Complications.** The complications of paratyphoid fever are those of typhoid fever but they occur somewhat less frequently—hemorrhage, perforation, urinary tract infections and in older patients circulatory collapse, bronchopneumonia or thrombophlebitis with pulmonary embolism. The septicemic forms of infection, often due to organisms of the supeptifer (*C*<sub>1</sub>) group, may result in the development of purulent foci of infection, particularly in the bones and joints but also in the meninges, pleural cavity and elsewhere. Gastroenteritis may result in dehydration and acidosis with serious results in the infant or debilitated elderly patient.

**Diagnosis.** The diagnosis of salmonella infection is a bacteriological one made by isolation of the organisms from blood, feces, urine or some local focus of infection. It may be suspected from a rise in the titer of O agglutinins for any organism of the homologous group or of H agglutinins for the infecting or a serologically related strain. The agglutination reaction is of more value in cases with blood stream invasion than in gastroenteritis. Invasion of the blood occurs in the early stages of paratyphoid fever with later appearance of organisms in the stools, while in most septicemic cases the organism may be isolated from the blood, urine or from local foci of infection but rarely from the stool. In gastroenteritis due to salmonella in contrast to bacillary dysentery, organisms are more

readily isolated from the stool later in the disease than at onset and frequently persist into convalescence.

Although a definite diagnosis can be made only bacteriologically, salmonella infection should be suspected in any case of unexplained fever, particularly one in which leukopenia or gastrointestinal or joint symptoms occur. In such cases differentiation from brucellosis or if rose spots are seen from one of the rickettsial diseases may be difficult. Meningitis and pneumonia may be confused with salmonella infections since leukocytosis, meningismus and cough frequently occur in salmonella infections with a rapid onset. *Salmonella gastroenteritis* must be distinguished from epidemic nausea, vomiting and diarrhea ("intestinal flu") which is probably a viral disease from poisoning from toxins elaborated by staphylococci, streptococci or other organisms in the food before ingestion. The first can be distinguished only on epidemiological grounds as a cold weather disease with a short incubation period, apparently spread by droplet infection. Food poisoning develops in a few hours after ingestion of the food. Bacillary dysentery may be indistinguishable except bacteriologically and in all instances of gastroenteritis in which abdominal pain is severe, differentiation of salmonella infection from acute appendicitis may be difficult, particularly as diarrhea may occur when the appendix is retrocecal. Elevation of the leukocyte count and localized pain and tenderness are the most helpful leads and suggest the need for a surgical approach. Instances of appendicitis with rupture due to salmonella infection have been described.

**Prognosis.** The prognosis depends on the virulence of the infecting organism and the condition of the patient. Septic infections due to *S. choleraesuis* have a high case fatality rate (26 per cent in Seligmann's last series). This is nearly five times as high as the case fatality rate of 5.1 per cent for all salmonella infections in his 1107 civilian cases which should be contrasted with a rate of 0.12 per cent in 809 Army cases. Age has an important bearing on mortality as in many other infections. Most deaths occur in older people. In children the infection though frequent is apt to be relatively benign except in very young infants.

**Treatment.** Acute gastroenteritis seldom requires more than symptomatic treatment—restriction of food intake to liquids and bland soft solids and if necessary repair of dehydration and provision of fluid

by the parenteral route. In a few instances the use of antispasmodics such as tincture of belladonna or atropine or such time honored remedies as bismuth subcarbonate and paregoric may be necessary to control severe cramps.

Enteric fever, septicemia and severe gastroenteritis should be treated with chloramphenicol or a tetracycline in full doses (50 to 60 mg per kilogram in adults per 24 hours in four to six divided doses) continuing for seven to ten days after the patient has become afebrile. The objective is symptomatic cure; positive stool cultures frequently persist. Unlike *S. typhosa* the other salmonellas are by no means uniformly susceptible to chloramphenicol (or the tetracyclines). Consequently the physician may encounter a salmonella enteric fever with bacteremia that will remain relatively unaffected by chloramphenicol (or tetracycline) therapy. In such circumstances if the patient is seriously ill it may be appropriate to administer an adrenocorticotrophic hormone for a few days in addition to the drug therapy and to continue the latter alone thereafter.

**Prevention.** Sanitation is the key to control of these infections. However the fact that many persons may be temporary carriers without symptoms of infection makes the problem of control difficult. If meat and eggs are adequately cooked, water and milk supplies controlled and fresh food is properly handled, those infections which depend on a heavy dose of organisms should seldom occur. Paratyphoid fever may occur as a result of a small infecting dose. In view of the frequency of infections due to group C in this country it is surprising that the latter have not been included in the standard typhoid-paratyphoid A and B vaccine. However, protection by vaccination is only relative and under conditions of heavy exposure infections may occur despite immunization.

## Infections with the Coliform, Proteus and Pseudomonas Groups of Bacilli

**Definition.** The various forms of infection caused by the gram negative aerobic bacilli normally present in the intestinal tract may be considered together under this heading.

**Bacteriology.** The coliform bacilli, most of which are motile, are differentiated from the salmonellas by their ability to ferment lactose. There are two main types: *Escherichia coli* (*B. coli*) the predominant organism in the gastrointestinal tract of man and animals, and *Aerobacter aerogenes* (*B. lactis aerogenes*) usually capsulated, which is also found in the bowel but derived primarily from vegetable sources. Strains intermediate between the two classic representatives of the colon aerogenes group have been described, while the *paracoliform* bacilli, which ferment lactose slowly, occupy a position between them and the salmonellas. The concept of a whole spectrum of organisms in the enteric group is further strengthened by the finding of some of the somatic antigens of the salmonellas in certain strains of coliform bacteria.

*Klebsiella pneumoniae* (Friedlander's bacillus) is morphologically similar to *Aerobacter aerogenes* but is more virulent and may be isolated from the respiratory tract or from the bowel in a small percentage of normal people. It occasionally produces gastroenteritis but is known chiefly as the cause of severe pulmonary infections. *Alcaligenes faecalis*, a motile organism found in normal stools, may be confused with the enteric pathogens by its failure to ferment lactose in differential media but is identified by the lack of fermentation when grown in media containing the standard sugars. This organism has occasionally been isolated in urinary tract infections and in cases of gastroenteritis, bacteremia or meningitis in infancy.

The *Proteus* bacilli are pleomorphic, non-lactose fermenting organisms characterized by active motility which gives rise to spreading growth on solid media. These organisms, although widely disseminated in decaying organic matter and feces, are present in large numbers in stools only in abnormal circumstances. *Proteus vulgaris* and *P. morganii*, the two species usually isolated from human infections, are active urea splitters with the liberation of ammonia.

*Pseudomonas aeruginosa* (*B. pyocyaneus*) is a motile aerobic bacillus capable of producing two water soluble pigments—the bluish pyocyanin and fluorescein which is yellowish green and fluorescent. Strains vary in their production of these pigments and some variants do not produce color. This organism is occasionally recovered in small numbers from normal stools but more often is found on the skin. It has been isolated from water, sewage and air and improperly sterilized instruments, solutions and surgical dressings.

**Etiology.** Recent work has implicated certain specific types of *E. coli* as the cause of epidemic diarrhea in hospitalized infants and occasional mild gastrointestinal upsets in adults. Since normally the coliform organisms are saprophytic inhabitants of the intestinal tract, it is only under special conditions that they gain access to the body cavities or tissue spaces and initiate infection.

In infancy resistance may be inadequate and these organisms may invade widely from foci in the respiratory or gastrointestinal tracts or in the newborn as a result of infection of the umbilical stump. Elderly patients likewise may suffer from bacteremia due to these organisms usually as a result of some complicating factor such as carcinoma, gallstones or renal calculi.

In the abdominal cavity surgical infections arise secondary to obstruction, perforation or interference with the blood supply of a hollow viscus. Puerperal infections due to colon bacilli may occur as a consequence of poor obstetrical technique or difficult labor.

Open wounds, chronic infections of the middle ear and ulcerations such as bed sores in areas of poor circulation, may become secondarily infected with gram negative bacilli, particularly *Proteus* or *Ps. aeruginosa*. The latter organism may be introduced accidentally into the thecal space or the urinary passages as a result of instrumentation. Indeed the development of meningitis following intraspinal anesthesia is almost invariably caused by *Ps. aeruginosa*.

Recently the intensive use of antimicrobial drugs has created a biological imbalance leading to elimination of susceptible strains of bacteria and their replacement by more resistant ones. This phenomenon may occur not only in the individual patient during therapy but also in the hospital environment where the presence of a large number of patients under treatment with antimicrobials may lead to a marked in-

crease in the population of drug resistant microorganisms in human carriers and in the dust. Coliform organisms and *Staphylococcus aureus* seem particularly prone to develop resistance during the course of treatment while *Pseudomonas aeruginosa* which is usually resistant to the ordinary antimicrobial drugs has become an important cause of superinfection in treated patients.

The most common disease produced by colon bacilli is urinary tract infection. It often arises as a complication of diarrheal disease and is frequently seen in elderly patients with constipation. Trauma to the urinary passages as from an indwelling catheter, stasis in the bladder or obstruction to the ureters predisposes to infection. Urinary tract infections may be caused by any of the coliform bacilli in pure or mixed culture but the majority are due to *E. coli* often in combination with the *Enterococcus* (*Streptococcus faecalis*). *Proteus* and *Pseudomonas aeruginosa* are usually encountered as secondary invaders in chronic urinary tract infections, particularly after instrumentation and in chronic pulmonary infections.

The incidence of urinary tract infection is considerably higher in women than men and diabetics are particularly subject to the disease. In men some obvious mechanical difficulty such as neurological bladder prostatic hypertrophy, urethral stricture or calculus can usually be found to account for the infection.

**Morbid Anatomy.** Acute infection with these organisms produces purulent inflammation. In cases of bacteremia in infants there is a tendency to localization in the kidneys, meninges, lungs and serous cavities. Contrary to earlier opinion the lesion in pyelitis has been found to involve the renal parenchyma as well as the pelvis and ureters so the term "pyelonephritis" has come into common use for this condition.

The characteristic local lesions of the skin and gastrointestinal tract which occur in infections due to *Ps. aeruginosa* are ulcerative or gangrenous. On microscopic examination there is necrosis around a thrombosed small blood vessel with large numbers of bacilli in the surrounding tissue and relatively little reaction. Leukopenia and hypoplasia of the bone marrow have been observed in some severe infections.

**Pathological Physiology and Chemistry.** All the gram negative enteric bacilli have potent endotoxins associated with their somatic antigens. Consequently invasion of the blood stream by these organisms

gives rise to the same symptoms as those which follow the intravenous injection of typhoid vaccine—chills fever headache nausea malaise and shock.

Certain of these organisms particularly *Proteus* produce large amounts of ammonia from urea which results in an alkaline urine and a tendency to the formation of calculi containing calcium magnesium carbonate and phosphate.

**Symptoms** The symptoms of colon bacillus infection are of two types local and constitutional. The local symptoms are determined by the particular organ infected—gallbladder bile ducts appendix urinary bladder kidney—more than by the organism concerned and detailed descriptions of these conditions will be found in appropriate sections of this book. The constitutional symptoms are most marked in cases of peritonitis suppurative pyelophlebitis cholangitis acute pyelonephritis or whenever there is bacteremia. In children and adults severe shaking chills followed by episodes of high fever malaise headache nausea and sometimes vomiting are the rule. Relative bradycardia may be seen. Where there are purulent foci leukocytosis with a predominance of polymorphonuclear cells is marked and anemia develops rapidly. In newborn infants the picture of sepsis with these organisms which may involve middle ears lungs kidneys and meninges may be one of prostration with subnormal temperature vomiting diarrhea and convulsions although fever leukocytosis jaundice and hepatosplenomegaly are often seen in instances of ascending infection from the umbilical stump. Although acute pyelonephritis is generally associated with prominent constitutional symptoms many urinary tract infections remain chronic throughout and may manifest themselves only by fatigue backache and slight malaise.

Superficial infections with *Ps. aeruginosa* are relatively asymptomatic but when invasion occurs this organism produces serious toxic manifestations. In infants in whom infection of the gastrointestinal tract may cause ulceration at any point along its course from mouth to anus prostration vomiting diarrhea abdominal distention with paralytic ileus and a tendency to pancytopenia may be observed. In bacteremic cases skin lesions may be primary or metastatic. Most characteristically these consist of a bright pinkish areola surrounding a gangrenous center (ecthyma gangrenosum). Other types of rashes including rose spots have been observed particularly in certain cases where the clinical picture

has resembled that of typhoid fever. In adults bed sores or chronic foci of infection in the genitourinary tract may serve as the sources of bacteremia which is apt to give severe chills high fever and prostration. Meningitis is the commonest metastatic complication of bacteremia but may also develop as a result of the accidental introduction of organisms on lumbar puncture or ventricular drainage. Pneumonia and arthritis are also seen as local manifestations of *Pseudomonas* infection. Ulceration of the cornea due to *Ps. aeruginosa* usually leads to a destructive panophthalmitis unless vigorously treated. Although leukopenia anemia and thrombocytopenia have been observed in severe cases of *Pseudomonas* infection moderate leukocytosis occurs more frequently.

**Diagnosis** In local infections the colon bacillus may be suspected from the fecal odor and greenish color of the pus whereas *Pseudomonas* should be considered whenever pus or discharges have a bluish or greenish yellow color. Diagnosis can be made only by bacteriological methods the finding of gram negative bacilli on smear and their isolation on culture of the local lesion. Blood culture should be performed in cases with high fever and a properly collected specimen of urine examined and cultured in all cases of suspected urinary tract infection.

**Prognosis** In severe infections due to the colon group prognosis depends on several factors. First pure colon bacillus infections have a better prognosis than mixed infections particularly in the abdomen where the presence of pyogenic cocci and anaerobic bacilli adds greatly to the severity of the disease. Second the age and condition of the patient make a tremendous difference. Infants and elderly patients do badly. Third the type of anatomical difficulty which gives rise to the infection has a marked bearing on prognosis.

In the urinary tract the degree of destruction of the renal parenchyma and the possibility of remedying the obstruction to urinary flow will influence the outcome of the acute attack and the ultimate course of the disease. Urinary infections in diabetic patients and infections due to *Proteus* or *Pyocyanus* are apt to be resistant to therapy.

**Treatment** The treatment of these infections should be of three types first general supportive measures second antimicrobial therapy and third therapy of the local infection. The last frequently calls for surgical intervention in the case of intra

abdominal infection. In such cases as in other types of generalized or severe infections with the gram negative bacilli intensive chemotherapy is essential.

Supportive measures are particularly important in the early phases of gram negative bacillary infections while the invasive stage is being brought under chemotherapeutic control because the potent endotoxins liberated may produce severe prostration and circulatory collapse and because most patients are either very young elderly or debilitated. In addition to parenteral fluids and blood transfusions to combat anemia and support the circulation the administration of adrenocorticotrophic hormone, cortisone or hydrocortisone in combination with a vasopressor agent like 1 norepinephrine for two to three days may enable properly selected very ill patients to survive the initial toxicity of the infection.

The intelligent use of antimicrobial therapy in gram negative bacillary infections demands close collaboration between the physician and the laboratory because of the varied drug susceptibilities of members of this group of organisms and the tendency for resistant strains to emerge during treatment. For these reasons cultures should be obtained and the effect of the available drugs upon the strain in question determined *in vitro* whenever possible. In severe infections of the abdominal or pelvic viscera which are apt to be mixed infections the combination of penicillin and one of the drugs effective against bacteria of the coliform group (streptomycin, chloramphenicol or one of the tetracyclines in doses of approximately 30 to 50 mg per kg) should be used until an accurate bacteriological diagnosis can be made. A tetracycline drug or streptomycin and a sulfonamide represent the best drug regimens for the early treatment of known infections due to *E. coli* or *Aerobacter*. In the absence of laboratory data on drug susceptibility. With *Proteus* infections the situation is more difficult and streptomycin with chloramphenicol (or a sulfonamide) probably is the most reasonable initial therapy. However if a therapeutic response is not obtained after forty-eight hours of adequate dosage another drug of the group listed above should be tried. Polymyxin B (Aerosporin) is at present the most effective antimicrobial drug for the treatment of systemic infections due to *Pseudomonas aeruginosa* but because of its potential toxicity it should not be used unless a specific bacteriological diagnosis has been made. Average dosage is

2.5 mg per kg. Neomycin is the most useful drug for elimination of pathogenic *E. coli* from the stools.

Management of urinary tract infections should include the following:

- 1 Evaluation of the anatomical situation
- 2 Relief of obstruction if possible and care of disease of the large bowel
- 3 Forcing of fluids to maintain a free flow of urine thus washing out pus and cellular debris whenever this is compatible with chemotherapy
- 4 Adequate chemotherapy to relieve acute symptoms and cure the infection if possible
- 5 Careful follow up study in order to recognize and treat recurrences promptly

The treatment of chronic urinary tract infections should be carried out in cooperation with a skilled urologist and planned after careful bacteriological studies of the organisms involved because of the tendency to recurrence or the development of resistant organisms unless the mechanical factors responsible for the infection can be controlled.

The local treatment of chronic infections involving the skin, wounds, ears and bronchial tree in which gram negative bacilli may be involved cannot be considered in detail here but methods are constantly improving. The development of enzymatic therapy with streptodornase and streptokinase has represented an important advance in this field particularly in the treatment of *Pseudomonas* infections. Application of sulfonamides or penicillin to the skin should be avoided because of the danger of sensitization of the patient to their subsequent systemic administration.

**Prevention.** The prevention of serious infections of this type consists mainly in the prompt recognition and treatment of abdominal disease such as appendicitis and cholecystitis, the proper handling of labor, scrupulous cleanliness in the handling of open wounds and prompt institution of tidal drainage in neurological conditions in which control of the sphincters is lost for more than a few days. Above all it is important to consider infections of the urinary tract as potentially serious since they are prone to recur to induce the formation of calculi and to produce renal damage and even severe hypertension in some cases.

## Klebsiella Infections (Friedlander's Bacillus)

**History** The organism was discovered by Friedlander in 1882. It was first described as a coccus and as the cause of pneumonia. This gave rise to considerable confusion and to a bitter controversy especially with Fraenkel. The controversy was essentially resolved in 1886 by Weichselbaum who came around to the view now generally held, namely that pneumococcus is the chief etiological agent of pneumonia and that Friedlander's bacillus is the cause in a small percentage of cases.

**Bacteriology** Friedlander's bacillus *Klebsiella pneumoniae* (synonyms *Bacillus mucosus capsulatus* B friedlander, *B pneumoniae*, *Pneumobacillus Encapsulatus mucosus*) is an encapsulated short plump nonmotile gram negative rod which grows to form mucoid gelatinous colonies on agar and a slimy surface pellicle in broth. Organisms of the genus *Klebsiella* are often difficult to differentiate from other encapsulated species of the tribe *Escherichia* particularly those of the genus *Aerobacter*. There is considerable overlapping not only in the biochemical reactions which are still the most useful for clinical purposes but also in the groups which are based on the O or somatic antigens and in the types based on capsular antigens. More than 77 capsular types have already been identified.

**Occurrence and Pathogenicity** *Klebsiella* occurs in the respiratory passages of from 2 to 25 per cent of normal persons in the normal intestinal tract even in infants and in the respiratory tract of mice, guinea pigs and rabbits. *Klebsiella* has been found in soil, dust, air and water. The microorganisms are pathogenic for man producing characteristic acute and chronic pulmonary infections and also suppurative infections in the upper respiratory passages in the intestinal, biliary, genital and urinary

tracts and in serous cavities and meninges. *Klebsiella* can give rise to septicemia and pyemia. The microorganisms produce septicemia and widespread lesions when injected into mice, guinea pigs and rabbits.

## KLEBSIELLA PNEUMONIA

**Definition** *Klebsiella pneumoniae* is a specific acute infectious disease caused by *Klebsiella pneumoniae* and characterized by massive mucoid inflammatory exudate of lobar or confluent lobular distribution in one or more lobes of the lung with a tendency to necrosis and abscess formation. It is commonly known as Friedlander's pneumonia.

**Incidence and Distribution** *Klebsiella pneumoniae* constitutes from 0.6 to 13 per cent of all cases of pneumonia in different series averaging 1.1 per cent in over 17,000 cases (Julianelle). It has been encountered in most parts of the world and in all seasons. The disease is usually sporadic but contact cases and epidemics have occurred.

**Bacteriology** *Klebsiella* has been found in pure culture during the first days of the disease in sputum, lung and pleural fluids and in blood cultures and in direct smears and cultures from the blood and lungs at autopsy in rapidly fatal cases. The pneumonias are caused predominantly by type A strains which are found in about two thirds of the cases. Type B is next in frequency.

**Predisposing Factors** Pneumonia due to *Klebsiella* has its greatest incidence between the ages of forty and sixty years. Chronic alcoholism, malnutrition and general debility are encountered frequently in these cases. Antecedent simple upper respiratory infections are relatively infrequent. The disease may occur as a secondary infection following pneumonia due to other organisms particularly pneumococci or contrariwise it may be followed by infections with other organisms.

**Morbid Anatomy** The involved lung is heavy, voluminous and noncrepitant with massive consolidation (lobar or confluent lobular) of one or more entire lobes. Plaques of fibrin are found on the pleural surfaces. The cut section usually has a smooth but mottled gray-red or red-brown surface from which thick stringy mucinous exudate often oozes as if under pressure. The underlying lung often reveals soft areas in which alveoli appear liquefied and replaced by the mucinous exudate. In older lesions there may be gray-green purulent exudate with large areas of abscess forma-

tion Histologically the outstanding features are the necrosis of alveolar tissue the enormous numbers of encapsulated bacilli and the exudate consisting of polymorpho nuclear large mononuclear (alveolar epithelial cells or monocytes) and erythrocytes in varying proportions with only a small amount of fibrin The phagocytosis of klebsiella in an experimental pneumonic lesion may be seen in Figure 20 (page 116) in the section on Pneumococcal Pneumonia

**Symptoms and Course** The onset is usually with chill pleuritic pain cough and bloody sputum Profound prostration sets in early and delirium and distention are common Dyspnea and cyanosis also occur early and may be intense Sputum is usually copious but is often raised with difficulty because of its mucoid and sticky character it may appear rusty but is more often brick red or bloody and gelatinous resembling currant jelly Organisms are abundant in smears of such sputum Hemoptysis vomiting and diarrhea are frequent and jaundice is present in many of the severe cases Erythemas sometimes scarlatiniform occur and patients with bacteremia may have petechiae Herpes rarely occurs

Signs of consolidation may be made out early but more often the classic signs are absent and there may be only dullness and muffled breath sounds even when massive density is visible in the roentgenogram This is presumably due to plugging of bronchi with viscid exudate Moist rales may be heard over some areas of the lung Involvement of the upper lobes or of multiple lobes is more frequent than in pneumococcal pneumonia The fever may be sustained or irregular but usually ranges lower than in cases due to pneumococci

The disease may run a fulminating course ending fatally in twenty four to thirty six hours The average duration in Bullow's cases was about five and a half days Death is usually associated with peripheral vascular collapse pulmonary edema or extreme respiratory distress with out pulmonary edema Recovery is sometimes by crisis but more often it is by lysis and then may frequently be followed by the chronic type of pulmonary infections to be described later

**Laboratory Findings** The chief distinctive finding is the large number of characteristic bacilli in smears of the sputum Agar cultures made of the sputum directly yield the characteristic mucoid colonies usually in pure culture Blood cultures yield the same organisms in more than half of the cases and the organisms may be obtained almost

regularly in pure culture by lung puncture or from pleural exudates even when the blood culture is sterile Total leukocyte counts below 6000 per cu mm occur in more than one third of the cases In other cases there is a moderate leukocytosis with total counts reaching 25 000 or 30 000 per cu mm in the presence of purulent complications

Roentgenograms usually show marked density developing early Areas of rarefaction may appear later indicating abscess and cavity formation which in patients who survive long enough then shows evidence of healing and fibrosis

**Complications** The commonest complication is delayed resolution with abscess formation and fibrosis of the lung (see below) Pleurisy is frequent Empyema pericarditis meningitis nonsuppurative arthritis and superinfections with other organisms notably pneumococci and hemolytic streptococci have been noted Empyema and lung abscess which does not drain properly may require surgical intervention but this should be avoided in the latter instance if possible because a chronic sinus may result

**Diagnosis** Klebsiella pneumonia is suspected in any case of acute pneumonia with severe prostration occurring early especially if there is bloody gelatinous sputum The diagnosis is based on demonstrating the characteristic encapsulated bacilli in smears and cultures of sputum as the only or predominant organism They may be typed directly by the Neufeld method The disease in some of its stages may simulate acute pneumonias due to other organisms particularly pneumococcus pulmonary tuberculosis acute pulmonary infarction or bronchiectasis

**Prognosis** The mortality in primary acute cases when untreated averages about 80 per cent regardless of whether or not bacteremia is demonstrated this has been reduced to about 40 per cent in patients treated adequately with antimicrobial drugs The mortality in chronic or recurrent cases is appreciably lower

**Treatment** The general and symptomatic treatment for klebsiella pneumonia is the same as for severe cases of pneumococcal pneumonia Since peripheral vascular collapse is not uncommon in klebsiella pneumonia the blood pressure should be determined frequently and norepinephrine administered promptly in the presence of hypotension Antimicrobial therapy consisting of both streptomycin or dihydrostreptomycin and chloramphenicol should be instituted at the earliest moment The strep

tomycin should be given in a total daily dosage of 20 gm administered intra muscularly in two equally spaced doses. The chloramphenicol may be given by mouth in a total daily dosage of 30 gm administered in divided doses at six hour intervals. As the patient recovers the daily streptomycin dosage may be lowered to 10 gm but the streptomycin chloramphenicol therapy should be continued for a total period of at least two weeks. One of the tetracycline drugs may be substituted for the chloramphenicol in the above regimen but the chloramphenicol is preferable.

### CHRONIC KLEBSIELLA INFECTIONS OF THE LUNGS

**Definitions** These are subacute or chronic infections of the lung caused by *Klebsiella pneumoniae* with a protracted and relatively benign course and expectoration of purulent nonputrid and sometimes bloody sputum. Characteristically they are accompanied by abscess formation, bronchiectasis and pulmonary fibrosis and exhibit a tendency to exacerbations of acute pneumonia.

**Occurrence, Etiology and Pathogenesis** The exact incidence of these chronic forms is difficult to establish but they are much less frequent than the acute *Klebsiella pneumoniae*. Probably many cases go unrecognized and are included as tuberculosis or as other chronic pulmonary infections. The relation of the *Klebsiella* to the disease is based upon finding the organism in large numbers and often in pure culture in sputum in abscess or pleural fluid or in blood cultures during acute phases. Other organisms are also found in varying numbers in the later stages.

**Morbid Anatomy** Grossly the lungs present a picture of confluent pneumonia with fibrosis, bronchiectasis and abscess formation. The walls of the cavities consist of bundles of collagen fibers bearing connective tissue cells without the remains of alveolar walls. Bronchi showing bronchiectatic changes often blend with foci of acute inflammation and with abscesses.

**Symptoms and Course** The disease usually begins as an acute *Klebsiella pneumoniae* with slow recovery over a period of weeks during which abscess formation and fibrosis of the lung occur. In some cases there is a milder course from the start with low grade persistent fever, cough with copious purulent sputum, loss of weight and recurrent pleurisy. The sputum is not foul unless there is a mixed infection and intermittently becomes blood streaked

brick red or grossly bloody. The disease may go on for several weeks and end in complete symptomatic recovery with apparent clearing of the lesions on the roentgenogram or it may persist for many months or years. Chronic abscess formation and bronchiectasis with fibrosis tend to reproduce the disease and give rise to relapses and frequent hemoptysis particularly after acute respiratory infections. In more than three fourths of the cases one or both upper lobes are involved.

**Laboratory Findings** The typical encapsulated bacilli are always present in large numbers. Secondary organisms including pneumococci, staphylococci, influenza bacilli and other common mouth inhabitants may also be abundant. Bacteremia is less common in these chronic cases but positive blood cultures have been obtained during the original acute pneumonia and during exacerbations. Specific antibodies may be demonstrated early and persist for a few weeks. Low grade leukocytosis is the rule except during acute phases when there may be leukopenia. Roentgenograms of the chest show thin walled cavities with or without fluid and later there is fibrosis and retraction of the upper lobes simulating tuberculosis.

**Complications** Recurrent pleurisy is frequent. Empyema usually encapsulated with thick mucoid pus may occur with or without relation to abscess formation in the lung. Serous effusions are encountered which may be sterile or infected and may occur in patients who have purulent empyema elsewhere. Recurrences of acute pneumonia and hemoptyses are the rule. Atrial thrombophlebitis with acute arthritis has been encountered. Pericarditis and meningitis may occur as terminal events.

**Diagnosis** In cases seen during the acute phase the diagnosis is made when there is slow recovery and evidence of abscess formation with copious sputum. The disease may be simulated by pulmonary tuberculosis with cavitation. Many patients with the latter diagnosis in whom tubercle bacilli are not found are shown to have chronic *Klebsiella* infections. The diagnosis depends on repeatedly demonstrating the characteristic encapsulated bacilli as the only or predominant organism in smears and cultures. Staphylococcal pneumoniae, bronchomycoses, lung abscess, bronchiectasis and tumors of the lung must be considered in the differential diagnosis.

**Prognosis** The mortality is said to be about 25 per cent. Death may occur in the

original attack after a slowly progressive illness of several weeks or months or it may occur during an acute exacerbation of pneumonia with the same or other organisms or as a result of complications such as pericarditis meningitis or after operation for empyema or lung abscesses. Some patients apparently recover completely while most of the others continue to have signs and symptoms for many years.

**Treatment** Intensive antimicrobial therapy as outlined for the management of acute *Klebsiella pneumoniae* should be employed. Empyema usually necessitates rib resection which may also be necessary for large pulmonary abscesses which fail to drain. Conservative treatment is recommended for abscesses in general in the hope that they will eventually drain into a bronchus. In cases in which the chronic *Klebsiella* infection is localized to a lobe or pulmonary segment some form of excisional surgery should be considered.

#### KLEBSIELLA SEPTICEMIA

**Definition** This is a local or generalized infection caused by the *Klebsiella pneumoniae* frequently accompanied by bacteremia and associated with localized purulent infections in one or more organs.

*Klebsiella* bacteremia is relatively uncommon and is seen less frequently than bacteremia caused by streptococci, staphylococci, colon bacilli, meningococci or pneumococci. Several types of generalized *Klebsiella* infections with bacteremia are described: (1) a pure bacteremic type which has an acute and rapidly fatal course; (2) a pyemic type with multiple abscesses in many organs; (3) bacteremia with symptoms referable predominantly to one organ; and (4) one which is secondary to infection with other organisms.

**Portal of Entry** The organisms may gain access to the blood stream from any of the following foci: the middle ear, the lungs, particularly when there is thrombophlebitis of the pulmonary vein, the intestinal tract, commonly in infants, the liver, especially when there is thrombophlebitis of the hepatic or portal vein, the urinary tract, the genital tract, notably the prostate in males, the adnexa or the puerperal uterus in females. A large proportion of the cases are so-called cryptogenic and the original focus cannot be determined even at autopsy. Little is known concerning the type distribution of *Klebsiella* in these cases. The organism is recovered in pure culture from the blood and from foci of suppuration and frequently from the urine.

**Occurrence and Predisposing Factors** Many of the cases occur in infants, children and young adults of both sexes, differing in these respects from the pneumonias. Alcoholism, cirrhosis of the liver and diabetes are particularly frequent in the adult cases.

**Morbid Anatomy** The dominant feature is the finding of metastatic abscesses in the liver, lungs and kidneys. Only those in the lungs are characteristic. The pus in the abscesses is usually mucoid and tenacious and the characteristic organisms are readily found in large numbers in smears and are usually in pure culture. Ulcerative endocarditis, meningitis and involvement of serous cavities are sometimes encountered.

**Symptoms and Course** The onset may be abrupt with severe chills or may be insidious with high continuous or intermittent fever and general malaise, with or without chills. Vomiting and diarrhea are common. Rash occurs and may be scarlatiniform, maculopapular or petechial in character. There is an acute fulminating type described (Blumer and Laird) with a hemorrhagic septicemia in which intestinal symptoms predominate and in which changes in the intestine similar to those of typhoid fever are found at autopsy. In some cases, particularly in adolescents, the course may simulate that of typhoid fever in every respect, including the leukopenia. In others the picture is dominated by some local lesion such as abscesses of the kidney, lungs, prostate or liver, or by a cholecystitis with ascending infection, or there may be perforation of the intestine with peritonitis. In the cases with liver abscesses, jaundice may be prominent. The disease may be of short duration or last for several weeks. Meningitis or endocarditis may occur terminally.

**Diagnosis** This depends on finding the *Klebsiella* in blood cultures or on demonstrating the organisms in characteristic pus from metastatic lesions.

**Prognosis** The mortality is high but except in cases with pyemia, recoveries are recorded in all types of cases, including some which have shown a persistent bacteremia for some time. The prognosis is particularly favorable in cases in which there is a predominant focus such as the prostate, which is accessible to surgical drainage.

**Treatment** Streptomycin, along with chloramphenicol, should be given in full doses as in the cases of pneumonia. Accessible foci should be drained surgically.

## Bacillary Dysentery

**Definition** Bacillary dysentery is an infectious disease characterized by pyogenic inflammatory lesions of the large bowel. The cardinal clinical symptoms are diarrhea, tenesmus and abdominal cramps. In severe cases mucus and pus are characteristically found in the stools. Blood may or may not be present. The causative organisms belong to the genus *Shigella*; hence the use of the term *Shigellosis* to include all types of infection caused by them. The disease is widespread throughout the world but is particularly prone to appear in epidemic form in the tropics.

**History** Bloody diarrhea accompanied by tenesmus and abdominal pain was recognized as a clinical entity by Hippocrates in the fourth century B.C. Herodotus attributed the defeat of the Persian Army in 480 B.C. in part to dysentery and since that time it has been an important scourge of military campaigns. Only in World War II was field sanitation sufficiently developed to prevent epidemic outbreaks of the disease. The separation of amebic and bacillary dysentery on clinical, epidemiological and pathological grounds took place in the latter part of the nineteenth century. In 1898 Shiga identified *Shigella dysenteriae* Type I as the causative agent in an outbreak of the disease occurring in Japan and in the course of the next twenty years Flexner, Sonne and Schmitz isolated related organisms from patients suffering from dysentery in other parts of the world.

**Etiology** The causative agents of bacillary dysentery are bacteria belonging to the genus *Shigella*. These organisms are slender nonsporulating gram negative rods which are neither motile nor encapsulated. They are facultative anaerobes which show optimum growth at 37° C and are not fastidious in their growth requirements. On the basis of biochemical and antigenic studies several distinct species have been recognized within the genus.

The more important pathogens are *Shigella dysenteriae* Type 1 (Shiga bacillus) and Type 2 (Schmitz bacillus), *Shigella flexneri* (Flexner subgroup of paradyenteric bacilli multiple antigenic types), *Shigella boydii* (Boyd subgroup of paradyenteric bacilli multiple antigenic types) and *Shigella sonnei* (Sonne bacillus).

Of these species only *Shigella dysenteriae* Type 1 produces a soluble heat labile exotoxin. This is neurotoxic in nature and its relation to the pathogenesis of the disease remains uncertain. The cell substance of dysentery bacilli (in common with other gram negative organisms) contains a relatively heat stable endotoxin which when injected parenterally into small mammals causes diarrhea, weight loss and inflammation of the gastrointestinal wall which may progress to actual ulceration. While it is plausible to assume that the release of this endotoxin in the gut wall as a result of autolysis of the bacterial cells is related to the production of the specific lesions, direct proof of this is lacking. The pathogenesis of the disease process is not clear.

**Epidemiology** The portal of entry for the dysentery bacillus is the gastrointestinal tract; the usual vehicle is feces contaminated food, water or fingers. During the acute stage of the disease the organisms are excreted in large numbers in the liquid stools. This process may continue during convalescence or even into the period when the patient has become asymptomatic. Dysentery in epidemic form is likely to occur at times when large groups of people are massed together under conditions of defective sanitation, e.g. armies in the field, refugee camps, overcrowded asylums for the mentally deficient. Direct person to person transfer of fecal material is presumably the most important method of spread under such conditions (Watt). Tropical conditions by favoring the mechanical spread of the disease by flies and other arthropods are propitious for the development of epidemic disease. Although in temperate climates the disease tends to appear in endemic rather than epidemic

form it is nonetheless widespread. In these conditions the symptomless carrier is presumed to represent the usual source of infection. The incidence of the disease in these areas is usually greater in the warmer months of the year.

**Morbid Anatomy** Bacillary dysentery is a pyogenic inflammation of the mucous membrane of the large bowel which may extend to involve the lower ileum as well. The earliest changes are generalized hyperemia and edema of the mucosa. Focal ulceration occurs as the surface tissue becomes necrotic and sloughs off. These ulcers show sharp well defined margins in contrast to the undermining lesions of amebic dysentery. In bacillary dysentery the ulcers do not extend as a rule beyond the muscularis mucosae and only rarely go on to perforation. The infectious process is essentially local being limited to the gut wall and invasion of the blood stream is an uncommon finding. Healing takes place by the formation of granulation tissue which is often pigmented. Scar tissue formation is common only if the ulcers are unusually deep and extensive.

**Pathological Physiology and Biochemistry** The frequent passage of copious liquid stools as a result of the inflammatory process involving the large bowel causes a significant loss of both water and electrolytes. As a result of the relatively greater loss of base (sodium and potassium) in the form of intestinal secretions acidosis develops which is accentuated if the patient is unable to take food by mouth. If fever is present the insensible loss of water in creases and dehydration is correspondingly more marked. In severe cases appreciable amounts of blood may be lost with the stools but in the uncomplicated infection it is rare for this to progress to the point where significant anemia develops. Interfering with the proper absorption of food stuffs long continued diarrhea results in significant malnutrition.

**Clinical Manifestations** The incubation period probably varies from one to six days with a median of approximately forty eight hours. Incubation periods of less than twenty four hours have been reported but are rare. The magnitude of the infecting dose and the general physical condition of the patient are factors which probably affect it.

The clinical severity of bacillary dysentery varies greatly from the very acute case in which the severity of the diarrhea and the prostration of the patient simulate cholera to the mild one in which they may be

no more than slight diarrhea for a few hours with the passage of no blood and but little mucus. The great majority of clinically recognized infections fall between these extremes.

The onset is usually abrupt. Fever and abdominal cramps are the initial complaints. Chilly sensations and even frank chills are occasional symptoms at this stage. Diarrhea follows within a few hours. The stools semisolid at first rapidly become watery and in all but mild cases are accompanied by the passage of mucus and pus and less frequently blood. The patient may have watery bowel movements as often as four to five times an hour. After a few hours the frequency of movement becomes less. Generalized abdominal cramps are succeeded by tenesmus and the relatively scanty movements may begin to show gross blood. Headache, lassitude and general prostration are prominent features of the severer cases. Nausea is a common complaint. Vomiting may occur but is rarely protracted.

**Physical examination** at this time shows an anxious patient complaining of generalized abdominal discomfort and scalding bowel movements. Evidence of dehydration, dry tongue and skin and drawn facies may be apparent in the more severe cases. Abdominal tenderness, most marked in the lower quadrants, is usually found and at times is accompanied by generalized muscle spasm. Occasionally this is sufficiently localized in the right lower quadrant to suggest acute appendicitis. Sigmoidoscopic examination reveals hyperemia and edema of the bowel wall accompanied by spasm and rigidity. Injection of the lymph follicles and areas of purulent exudate may often be seen as well. A normal or moderately elevated leukocyte count (10 000 to 15 000 cells per cu mm) is the usual finding. Leukopenia is occasionally encountered if this is marked and primarily granulocytic the prognosis must be guarded.

In the case of average severity to which supportive therapy is given the disease runs its course over a period of a week or ten days. Concomitant with a diminution in the daily number of stools is a decrease of tenesmus and a return of appetite and a sense of well being. Mild diarrhea may continue for some days after the tenesmus and anorexia have disappeared. In light cases strength and weight are regained in a matter of days if the attack has been severe the return to the normal state of well being may take several weeks. If the infection is complicated by preexisting mal

nutrition or debility or if opportunity for supportive therapy is not available at the onset convalescence is correspondingly prolonged

Conjunctivitis upper respiratory symptoms and signs of meningeal irritation are occasionally met with during the acute stage of the disease In the last instance lumbar puncture reveals a normal cerebrospinal fluid Toxic encephalitis and peripheral neuritis have been reported as rare complications of *Shigella dysenteriae* Type 1 infections

Arthritis has been reported as a late complication in a small (1 per cent) proportion of cases It usually occurs during the second or third week after onset of the acute disease at a time when complete recovery is about to be attained The process involves the larger joints in single or multiple fashion Migratory polyarthritis is less common Usually the inflammatory condition subsides completely and spontaneously within the course of a fortnight

In a minority of instances the disease may progress from the acute to the chronic state Low grade irregular fever may persist for some weeks accompanied by intermittent bouts of mild diarrhea during which the stools show mucus in varying quantities but rarely significant amounts of blood Although it has been suggested that this condition predisposes toward the development of ulcerative colitis and ileitis an etiological relationship has not been proved

**Diagnosis** The abrupt onset of fever abdominal pain and diarrhea accompanied by the passage of mucus and blood strongly suggests the diagnosis of bacillary dysentery particularly if similar cases are encountered simultaneously in the same household or community Atypical cases present more difficulty Microscopic examination of the stool should always be done if possible The gross findings of mucus and blood may be confirmed by examination of coverslip preparations of mucus previously emulsified in saline The exudate of bacillary dysentery is highly cellular with a great predominance of polymorphonuclear cells as opposed to the mononuclear exudate characteristic of protozoal infections

The specific diagnosis is made by the isolation and identification of the etiological agent Cultures are best taken either by sigmoidoscopy or by means of the rectal swab technique If stool culture must be resorted to the specimen should be brought promptly to the laboratory and cultured as soon as possible Since the organisms are

found in greatest numbers in the mucous exudate flecks of this material should be selected for culture Of the various differential media used for the isolation of dysentery bacilli S agar (Difco) and desoxycholate citrate agar are the most useful Once suspected colonies have been isolated they may be identified by the proper biochemical and serological techniques notably fermentation of carbohydrates and agglutination by specific antisera Since even in the best of circumstances it is not always possible to isolate dysentery bacilli from clinical cases that are otherwise typical a negative culture does not exclude the diagnosis

During the second week of the disease agglutinins appear in the patient's blood The serological diagnosis by the demonstration of these antibodies is unsatisfactory however since they develop irregularly and relatively late in the course of the disease In addition many healthy persons have significant agglutinin titers as a result of previous contact with the organisms This is particularly true in areas in which dysentery is widespread as in the tropics

**Differential Diagnosis** The differential diagnosis must include other infections characterized by diarrhea In contrast to bacillary dysentery amebic dysentery usually occurs sporadically the onset is insidious and the patient is not incapacitated in the early stages of the disease which however usually progresses to chronicity Sigmoidoscopic examination reveals the typical lesions while the finding of the specific amebas in the stools confirms the diagnosis Cholera may usually be excluded on epidemiological grounds as well as by the absence of excessive vomiting and of typical "rice-water" stools containing cholera vibrios Occasionally typhoid and paratyphoid fevers may be accompanied in their early stages by diarrhea but the onset is usually much less abrupt The diarrhea caused by salmonella food infections comes on suddenly and is often severe in addition the cellular exudate may resemble that of bacillary dysentery In such cases the differential diagnosis depends upon the isolation and identification of the etiological agent Food infection due to streptococci or staphylococci may usually be differentiated on the basis of the shorter incubation period more vomiting and the absence of mucus and cellular exudate in the stools

**Prognosis** In ordinary circumstances bacillary dysentery tends to be an acute self-limited disease which usually runs its course over a period of ten days without

an appreciable case fatality rate. Outbreaks of bacillary dysentery have been reported however in which the case fatality rate has been as high as 30 per cent. In general prognosis in any individual case depends upon three factors: (1) the species of infecting organism, (2) the age and general physical condition of the patient at the time of infection, and (3) the opportunities for supportive treatment and chemotherapy.

*Shigella dysenteriae* Type 1 has long been credited with causing a particularly virulent type of the disease which in Japan and India has been attended by a high mortality rate. Infections with this organism are fortunately rare in the United States and Canada. In these countries the predominating bacteria *Shigella sonnei* and various types of *Shigella flexneri* generally give rise to a milder form of the disease.

Persons in the extremes of life infants and the aged are less resistant to the disease and among them the case fatality rate is appreciably higher. Further persons debilitated by acute or chronic malnutrition, hardship, privations or other unfavorable conditions of living are particularly susceptible to its ravages. These environmental factors are undoubtedly responsible in part at least for the high case fatality rate accompanying epidemics of bacillary dysentery in the Far East.

If adequate supportive therapy is made available for the patient early in the course of his disease the prognosis is greatly improved. Under favorable conditions chemotherapy may play an important role in controlling the infection.

The importance of all these factors is borne out by the remarkably low case fatality rates observed in the British and American Armed Forces during the latter part of World War II.

**Treatment.** The rational aims of the treatment of bacillary dysentery are (1) supportive and symptomatic to maintain the patient's strength and to relieve his symptoms, (2) correction of the pathological disturbances of salt water and protein metabolism, (3) eradication of the infectious agent by means of antimicrobial agents.

**General Management.** During the acute phase of the disease complete bed rest is indicated. The use of a diaper of absorbent cotton or cellulose instead of a bedpan saves the patient from unnecessary exertion. Purging should be avoided since it merely increases the patient's discomfort. In severe cases expert nursing care is of vital importance. The patient should be isolated

kept warm and screened from flies. Sanitary precautions as for any enteric infection must be maintained and particular attention should be paid to the sterilization of excreta and of soiled bed linen.

The abdominal pain and discomfort may usually be relieved by the application of heat (hot water bottles, stupes, and so forth) to the abdomen plus the judicious use of sedatives and antispasmodic drugs. According to Thompson, White and Schafer the following prescription is particularly useful:

	Gm or Ml
Tincture of belladonna	8
Sodium bromide	10
Elixir phenobarbital to make	60
Directions	1 teaspoonful every four hours

In some instances these measures will not control the discomfort. Though the routine use of paregoric and other opiates is contraindicated because of the artificial intestinal stasis that they cause, a gravely ill patient can occasionally be tided over the acute episode by the parenteral administration of codeine (45 mg) or morphine sulfate (10 mg) which will usually give him a few hours' comfort.

Dehydration and acidosis resulting from loss of base in the intestinal secretions must be combated vigorously by use of supplemental parenteral fluids if an oral intake adequate to produce a daily urinary output of 1500 to 2000 ml cannot be maintained. In the average case the daily intravenous administration of 1500 ml of physiologic saline (9 gm of sodium chloride per liter) to which 75 gm of dextrose has been added suffices to correct the electrolyte balance and add much to the patient's comfort. Severe cases require more parenteral fluid which should be given in the form of 5 per cent dextrose in distilled water. Rarely is the acidosis so severe as to require the use of supplementary sodium lactate.

If the patient shows evidence of incipient vasomotor collapse or shock coupled with hemoconcentration, plasma should be given in amounts adequate to restore the hematocrit reading to normal. It is rarely necessary to give more than 500 ml for this purpose. It is important that dehydration be relieved before or at least simultaneously with the administration of the plasma. In the occasional patient who develops a significant anemia secondary to blood loss in the stools, whole blood transfusions are indicated.

The diet during the acute stage of the disease is best limited to clear fluids given warmed and in small quantities. With the

return of appetite and feeling of well being a bland low residue diet containing adequate protein and vitamins is given. The return to a full diet should be made gradually and cautiously. In severe protracted cases the oral or parenteral administration of supplementary vitamins may be advantageous.

**Antimicrobial Therapy** The broad spectrum antimicrobials the tetracyclines and chloramphenicol are markedly effective in the treatment of bacillary dysentery. The recommended dosage schedule for these drugs is 2.0 gm initially followed by 1.0 gm every twelve hours. This usually results in prompt disappearance of clinical manifestations and a rapid conversion from positive to negative cultures. It is advisable to continue specific therapy for forty-eight to seventy-two hours after the acute diarrheal manifestations have subsided. The occurrence of relapses due to the emergence of drug-resistant organisms has not constituted a significant problem as yet. It should be noted that the tetracycline drugs also exert a definite effect in amebic dysentery. This effect is apparently not exerted directly on the ameba but is a result of the influence of the drug on the intestinal bacterial flora. The fact that an undiagnosed dysentery appears to respond promptly to tetracycline therapy thus does not necessarily indicate that it is caused by *Shigella*. Since the tetracyclines are not considered the most satisfactory therapy for amebic dysentery if the possibility of amebic etiology is strong the patient should receive other therapy (see Amebic Dysentery).

The effectiveness of the sulfonamides in the treatment of bacillary dysentery has been considerably reduced in recent years by the frequent occurrence of drug-resistant strains. In the past sulfadiazine has proved to be the most effective of these compounds.

**Prevention** Although it is manifestly important to detect, isolate and treat all cases of the disease as soon as possible the prevention of bacillary dysentery by the eradication of the etiological agent is rendered impracticable by the existence of a significant number of asymptomatic carriers of dysentery bacilli. Strict attention to personal hygiene is most important. Adequate sanitation, proper safeguarding of food and water supplies, effective disposal of sewage and fly control are the most valuable public health measures. Bacterial vaccines have not been effective. Chemoprophylaxis employing the tetracycline drugs should be effective in theory but preliminary reports have not been encour-

aging. The usefulness of sulfadiazine as a chemoprophylactic agent has been limited by the rapid emergence of drug-resistant strains.

## Cholera

**Definition** Cholera is an acute infectious disease caused by *Vibrio comma* in which the primary seat of the infection is in the gastrointestinal tract. It is characterized by diarrhea, vomiting and dehydration which are extremely severe in typical cases.

**History and Geographical Distribution** Cholera has been known for centuries in India whence it spread to China in the seventeenth century. A number of pandemics occurred during the nineteenth and early twentieth centuries. The United States was invaded repeatedly but after 1873 practically all cases were stopped at seaports. In recent years few cases have been brought to this country. During and after World War I epidemics occurred in Europe. During World War II there were extensive epidemics in the Far East and smaller outbreaks in the Near East but the disease did not reach Europe or the Americas.

Cholera is always present in the region of the lower Ganges River in India. Its distribution is potentially world wide. Since World War II however as the result of improved sanitation and enforcement of the International Sanitary Regulations cholera has appeared only briefly outside India and Pakistan.

**Etiology** The specific cause of cholera is the *Vibrio comma* (*V. cholerae*) of Koch (1883). The organism is a short curved bacillus with a terminal flagellum. It is aerobic, grows on ordinary media, is motile, easily stained by the usual methods and is

gram negative. It is readily dissociated into R and S forms. Both H and O antigens are present. The cholera bacillus is one of a large group of vibrios and its identification necessitates the use of a specific agglutinating serum or of special cultural procedures when agglutination fails as occasionally happens.

**Epidemiology** The etiologic agent may persist in nature in favorable circumstances for a few days but it dies out in stools in one or two days. For this reason infection generally can be traced to patients in the immediate neighborhood. The existence of subclinical infections in the community probably explains the often apparently haphazard distribution of clinical cases. It is doubtful that true carriers exist although convalescent patients may pass virulent organisms for a short time. The most important sources of infection are patients in the incubation stage and those with mild symptoms. Cholera is acquired by the ingestion of food or drink contaminated by feces which contain the vibrio. Contaminated water is one of the most important means of spreading the disease. Flies may play an important role. The development of epidemics is seasonal, being favored as a rule by high temperature, high relative humidity and intermittent rains. Unless effective control is exercised an epidemic rapidly spreads through an unprotected population moving along lines of communication such as railway, steamship and air routes. Cholera is not however as readily communicable as was formerly thought for many exposed persons escape infection.

**Morbid Anatomy** The striking changes are the result of extreme dehydration. Rigor mortis is unusually marked. Dryness and shrinkage are everywhere apparent but in general inflammatory changes are absent. The blood is thick and scanty. The serous membranes have the look of ground glass and are somewhat sticky. The intestinal wall is cyanotic and congested. The lumen contains much grayish opalescent liquid often with no trace of fecal matter. Large areas of mucosa may be lost but localized ulceration is not present. The lymphoid tissue of the ileum is somewhat prominent. The kidneys may show marked congestion.

**Pathological Physiology and Chemistry** The cholera vibrio has its principal localization in the ileum. Organisms may be found in small numbers in the lungs and other organs but they are seldom if ever demonstrated in the blood. Cholera vibrios produce no exotoxin and their effects are at-

tributed to the liberation of a powerful endotoxin. The principal immediate effect of the infection is precipitate loss by the body of large amounts of fluid and salts as the result of profuse diarrhea and vomiting. The extraction of fluid from blood tissue spaces and tissues in turn is rarely equalled in any other condition except some cases of infantile diarrhea and extreme hemorrhage. The tissues become desiccated and the blood is concentrated to a high degree. Such extreme values may be encountered as 1.070 for specific gravity, 20 gm per 100 ml for hemoglobin concentration, 7,000,000 per cu mm for erythrocyte count and 75 for erythrocyte volume percentage. The concentration of plasma proteins is also increased. These alterations in the blood have a profound effect on the circulation. The blood pressure is greatly reduced and the cardiac output is much decreased. In part at least because of these circulatory changes renal function is gravely impaired.

Chlorides are lost with the fluid of vomitus but this loss is overbalanced by that of bases principally sodium from the bowel. The resulting shift in the acid base balance is accentuated by the retention of acid which results from renal insufficiency. Values as low as 7.1 have been recorded for pH and 138 milliequivalents per liter for total base in the blood. Urea and other nitrogenous substances are also retained as a result of renal insufficiency. After the liberal intravenous administration of fluids even though no alkaline solution is given alkalosis tends to be present for a time during recovery. In most cases death in the early stage is chiefly the result of dehydration while in the later stages it is due to renal insufficiency. An attack of cholera confers only limited immunity to subsequent infection.

**Symptoms** The incubation period is usually only one to three days, sometimes as many as five. In occasional instances premonitory symptoms of depression, lack of energy and simple diarrhea occur. The onset is usually sudden. It is characterized by voluminous watery stools, copious vomiting and great prostration. In many cases the speed with which the symptoms attain overwhelming proportions is striking. Stools are passed with great frequency and soon lose all fecal character. They are grayish and contain clumps of degenerating epithelial cells and mucus but little if any blood and no pus. The absence of tenesmus is often noted. Vomiting may occur suddenly without nausea or retching. After

a time the vomitus resembles the stools. As dehydration becomes marked there is great thirst but almost nothing taken by mouth can be retained. The features become gaunt and pinched and the eyes sunken. The skin is cyanotic and shriveled. Muscular cramps may be widespread and exceedingly painful. The voice becomes thick and feeble. A marked tachycardia develops and the pulse may be hardly perceptible. The blood pressure falls, the systolic level often reaching values below 60 mm of mercury. Venesection may result in only slight bleeding. The excretion of urine is diminished and may cease. In severe cases uremia often develops. The skin temperature usually falls below normal although the rectal temperature may be normal or even elevated unless the patient is in a state of complete collapse. Unless uremia develops the mind remains clear although patients are usually extremely apathetic. Complications other than those directly related to the disease are not common or characteristic. They are usually related to the previous poor health of the patient as in the instances in which clinical signs of avitaminoses appear or to poor treatment. Occasionally secondary infections may occur such as those causing parotitis.

Of great practical importance is the fact that in epidemics cases occur in which only malaise and simple diarrhea are present throughout the course.

**Diagnosis.** Information that there is cholera in the area in which a patient lives or from which he has recently come should suggest the possibility of cholera. The clinical picture is highly characteristic in ordinary cases and typical stools are highly suggestive. In differential diagnosis confusion may arise over acute bacillary dysentery, food poisoning, heat exhaustion, some forms of malaria (especially *falciparum* malaria) and other conditions associated with diarrhea and shock. Mild cases of cholera masquerading as dysentery or food poisoning may be overlooked. They are extremely dangerous for the public health. The ordinary clinical laboratory examinations of blood, urine and stool are not very helpful.

The specific diagnosis of cholera is made by identification by agglutination of *V. comma* derived from passed stools or better from samples obtained from the rectum. Characteristic forms seen in smears stained with dilute carbolfuchsin are suggestive but the finding requires confirmation. The organism may grow poorly or not at all on media usually used for other intestinal pathogens.

Cultures should be made from fresh specimens using peptone water at pH 8.4. After incubation at 37° C for six to eight hours the surface growth in which vibrios are concentrated if present should be examined microscopically. If suggestive forms are found subcultures are made by streaking on nutrient or infusion agar. After twenty-four hours suggestive colonies should be tested by the slide method with agglutinating serum specific for *V. comma*. When positive tests are obtained the colonies should be isolated and further confirmation should be sought in the biochemical reactions of the organisms and by macroscopic tube agglutination tests.

**Prognosis.** The outcome depends greatly on the patient's previous state of health and on the promptitude and quality of medical care. The course is usually short averaging three to five days. Death may take place however in a few hours or only after many days. The case fatality rate in epidemics among poorly treated patients is often 60 per cent. On the other hand when adequate treatment is promptly given it may be as low as 5 per cent.

**Treatment.** Strict isolation is indicated for both patients and proved carriers. Clothing, bedding and eating utensils should be boiled. Stools, vomitus and (because of the danger of their being contaminated) urines should be thoroughly disinfected as for typhoid fever. Because of the brevity of the acute stage the diet during that period is relatively unimportant. At best patients can retain only small quantities of fluid at this time. A soft diet may be given as soon as the patient desires it. When the temperature is below normal the patient should be kept warm. Such drugs as sedatives, hypnotics, laxatives, epinephrine and digitalis have no place in the treatment of the usual patient. The value of cholera bacteriophage is controversial. No therapeutic serum which is known to be effective is available. The use of antimicrobial agents is discussed later. Antihistaminics have been reported to be helpful in treating the peripheral circulatory failure (and renal insufficiency) but their value is not yet established.

**Replacement Therapy.** The prompt parenteral administration of adequate amounts of solutions suitable to replace the lost water and electrolytes is crucial. Failure to recognize this need or delay in action may result in the death of the patient. The intravenous route is best. Whole blood is not indicated in cholera. The value of plasma is uncertain and the rationale of its use is obscure. The main reliance should

be placed on physiological saline solution but it is customary in early cases to give limited amounts (500 to 1000 ml) of a hypertonic saline solution (sodium chloride 14 gm per liter). Only sterile distilled water which is free of pyrogens should be used to make solutions for intravenous injection. It is desirable to add sufficient dextrose to make a 5 per cent solution to any solution given and 10 mg of thiamine chloride for each 25 gm of dextrose but this should be done so that not more than 50 gm of dextrose are given in one hour or 400 gm in twenty four hours. Solutions should be given at body temperature.

No rule can be given for the amount of saline solution which may be required or the period over which its administration may be necessary. Patients with cholera generally need amounts of fluid rarely given for other diseases. On the other hand too much fluid of any type given in too short a time may precipitate a fatal issue. The patient must be closely and continuously observed. The blood pressure is the most important single guide to clinical judgment. Other helpful guides are the pulse rate, the color and consistency of the blood and the volume of urine. Signs that too much fluid has already been given are restlessness, palpitation, pain in the chest, coughing and edema. The best objective guide to treatment is the specific gravity of the blood. The most convenient suitable method is the copper sulfate procedure of Phillips and his co-workers. The higher this value is at the start of treatment the greater is the total volume of fluid required. As the specific gravity approaches its normal value (1.056 to 1.058) the rate of administration of fluid should be retarded. As a rule 2 liters of fluid are needed in the first two hours and more fluid every three or four hours for sometime thereafter. In the first twenty four hours 4 to 8 liters are often required and injections may have to be continued through the second twenty four hours or longer.

In many cases the loss of alkali is so great that replacement is indicated. The acidosis of cholera differs from that of diabetes or nephritis. In the acute stage the respiration is not a good guide to the condition. Ketone bodies are not to be expected in the urine because of cholera itself. The volume and reaction of the urine are important indications. If practicable determinations of the blood pH, carbon dioxide combining power and nonprotein nitrogen are helpful. Alkali replacement may be made by the intravenous injection of a

solution of sodium bicarbonate 18 gm and sodium chloride 6 gm per liter which should be prepared with the usual precautions. Certain advantages including greater ease of preparation are offered by one sixth molar solution of racemic sodium lactate. A good many patients need 500 ml of alkaline solution but this amount often suffices. Care should be taken not to overdo the alkaline treatment. In addition to sodium other electrolytes are undoubtedly lost especially phosphate and potassium. The ideal replacement solution should contain such additional electrolytes as may be depleted. A detailed statement however can be made only when more information about electrolyte balances in cholera and experience with the use of complex solutions become available.

**Chemotherapy.** No drug treatment should be used in cholera to the neglect of replacement therapy. The good results obtainable without using antimicrobial agents render difficult the evaluation of such agents. So far none of these agents has been proved to produce significantly lower fatality rates than those seen following good replacement therapy. A few observers have believed that the use of sulfonamides shortened the course (it is usually very short with replacement therapy alone). When chloramphenicol or oxytetracycline is given organisms disappear early from the stools but without clinical benefit. The general conclusion is that antimicrobial agents add nothing significant to what is accomplished by replacement therapy but may be of help in reducing the infectiousness of the patient for others.

**Prevention.** Since the spread of cholera is always closely associated with patients suffering from the disease, the isolation of such patients and the proper disposal of their excreta and vomitus are essential. Cholera is one of the few diseases subject to foreign quarantine. Strict control of the water supply of food and food handlers and of flies is necessary for cholera control. If the water supply is not subject to general control it should be boiled and then chlorinated. In areas where cholera is present raw food should not be eaten and all handlers of food should be frequently examined and closely supervised. All food should be thoroughly protected from flies and other insects. Insects should be controlled by proper use of appropriate preparations of DDT.

**Immunization.** Control measures should not be neglected because of immunization. Vaccination against cholera affords partial

immunity which lasts only three to six months. It is recommended only for persons through an area where cholera is known to be present. Two doses (0.5 ml and then 1.0 ml) of a reliable vaccine should be given at an interval of seven to ten days. If exposure continues, a stimulating dose of 1.0 ml is given every four to six months.

## Brucellosis

(Undulant Fever, Malta Fever)

**Definition.** Brucellosis is an infectious disease due to organisms belonging to the genus *Brucella*, the disease being transmitted to man from lower animals. The acute stage is characterized by fever, sweats, weakness, pains and aches, and few or no localizing physical abnormalities. Occasionally, the same manifestations predominate in a chronic illness enduring for months or years.

**History.** Brucellosis constituted a febrile illness which puzzled the medical personnel of the British Army and Navy stationed in the Mediterranean area during the latter part of the nineteenth century. It appeared to differ from paludism (malaria) and enteric fever (typhoid). Marston, a Royal Army surgeon, presented a report of his own illness in 1863, which was an accurate clinical description of brucellosis. The etiologic agent was described by David Bruce in 1887. Bang in Denmark reported in 1897 the recovery of another species, *Brucella abortus*, from aborting cattle, while Traub isolated a third species, *Br. suis*, from aborting sows in 1914. Alice Evans differentiated strains of *Br. melitensis* from *Br. abortus* by serological methods and predicted correctly that human disease would result from drinking raw cow's milk. The classic monograph, "Mediterranean, Malta or Undulant Fever," by Hughes, appeared in 1897. Wright and Semple described the agglutination test for brucellosis in 1897. The epidemiology of brucellosis on the island of Malta was clearly defined by the brilliant reports

of the Mediterranean Fever Commission issued between 1905 and 1907.

**Etiology.** At least three species of *Brucella* are known, each of which is commonly identified with one of three animal species. They are *Br. melitensis* (goat), *Br. suis* (hog) and *Br. abortus* (cattle). *Brucella* are small gram-negative rods which are nonmotile and do not form spores. Growth is supported in liver infusion broth, tryptose phosphate broth, or trypticase soy broth. The combined liquid-solid medium of Castaneda with tryptose phosphate broth contained in a rectangular flask and tryptose phosphate agar distributed along one of the sides of the bottle affords a simple and safe method of handling *Brucella* cultures. Primary isolation of *Br. abortus* requires about a 10 per cent displacement of air by carbon dioxide. Differentiation of the three species is based upon biochemical reactions, serological tests, and the resistance of the organisms to the bacteriostatic action of various dyes.

**Morbid Anatomy.** *Brucella* localizes intracellularly in the tissues of the reticulo-endothelial system, particularly the lymph nodes, bone marrow, liver, and spleen. The initial cellular response to the organisms is the appearance of mononuclear and epithelioid cells, and then the formation of tubercles or granulomas having foreign body and Langhans types of giant cells. This pattern of tissue reaction is characteristic of brucellosis but is not specific. A similar type of cellular response may be encountered in some instances of sarcoidosis, tuberculosis, and syphilis. Sometimes *Brucella* induces necrosis of the tissues, and small abscesses may be seen in the parenchyma of the liver, spleen, and occasionally in the osseous tissue of the vertebrae and long bones. Caseation is not a feature of brucellosis. *Brucella* may localize in other organs or tissues such as the testicles, ovaries, meninges, and endocardium.

**Epidemiology and Pathogenesis.** The natural reservoir of brucellosis is in domestic animals, especially cattle, hogs, and goats. In animals, *Brucellae* tend to localize more abundantly in the mammary gland and in the pregnant uterus. Healthy appearing animals may shed large numbers of organisms in the milk for months or years, and the disease may provoke abortions in pregnant animals. Man contracts the disease by direct contact with infected animals or contaminated secretions and excretions. The organisms gain entrance through small abrasions

of the skin Human disease is also acquired through the ingestion of raw milk and fresh cheese prepared from unpasteurized milk The disease is rarely transmitted from human to human Brucellosis is primarily an occupational disease and involves rural populations much more frequently than city dwellers The disease occurs most often in farmers livestock producers meat packing plant employees and veterinarians Children are more resistant to brucellosis than are adults

In general *Br. abortus* produces a milder disease than that caused by *Br. suis* or *Br. melitensis* Not infrequently however *Br. abortus* may produce a severe even a fatal illness While the principal habitat of *Br. abortus* is cattle it has been recently established that this species occurs in hogs under natural conditions The more invasive *Br. melitensis* is traditionally associated with goats but in recent years naturally infected hogs have been found infected with this species in the midwestern area of the United States and an increasing number of human cases have occurred as a result of contact with infected porcine tissues Much less frequently *Br. melitensis* resides in cattle *Brucella suis* is most often found in hogs but invasion of cattle has occurred Epidemics of human brucellosis have been traced to raw cows milk containing *Br. suis* Except for unusual circumstances human brucellosis is a sporadic disease Because different degrees of illness are caused by the three species of *Brucella* it is well for physicians in any given geographic area to know what species of domestic animal is harboring the organisms and what species of *Brucella* is causing human disease In Minnesota and in Wisconsin most human cases are due to *Br. abortus* but in Iowa *Br. suis* is more commonly the cause of human disease In Mexico human brucellosis exists almost as an epidemic disease being due entirely to *Br. melitensis* However in Puerto Rico *Br. abortus* is the cause of human disease

Little is known about the invasive properties of *Brucella* The bacterial cells produce no exotoxin In common with other gram negative organisms *Brucella* do possess an endotoxin which participates in the pathogenesis of the illness After invasion of the tissues the organisms reside and very likely proliferate within the host's cells This intracytoplasmic parasitization may account for the chronicity of the disease both in animals and in man Hyper sensitivity to *Brucella* antigens is an outstanding feature of brucellosis which

probably contributes to the symptomatology of both the acute and chronic manifestations of the disease

**Symptoms and Signs** The incubation period is usually between five and twenty-one days but in an occasional patient the latent period between the entrance of *Brucella* into the body and the appearance of symptoms may be as long as six to nine months Brucellosis may have an abrupt onset with chills fever and sweats indistinguishable from many other febrile conditions In many instances the disease begins insidiously and it is only after days or weeks that an apprehensive patient seeks medical advice because of an ill-defined incapacitating illness An almost constant symptom of brucellosis is weakness Patients may feel reasonably comfortable while in a resting state but even the slightest physical exertion may induce extreme fatigue and exhaustion A feeling of chilliness and less often frank chills may precede a rise in temperature Profuse nocturnal sweats are a common manifestation Generalized aches and pains occur frequently and often there are headaches and pain over the thoracolumbar spine Abdominal pain may be generalized or localized to any one of the quadrants Arthralgia may occur with periarticular swelling but rarely is the tissue over the joints reddened and hot Anorexia and constipation are predominant gastrointestinal complaints though the illness may be ushered in with diarrhea A nonproductive cough may be present but symptoms referable to the upper respiratory tract are not prominent The symptomatology in brucellosis due to *Br. abortus* is summarized in Table 1 Examination of the patient may reveal few or no physical abnormalities The physical findings in cases of brucellosis due to *Br. abortus* are shown in Table 2 Almost one half of the patients have enlarged peripheral lymph nodes or splenomegaly Hepatomegaly is often present though jaundice is rare

As the illness extends beyond the first few days the manifestations of the disease become established in a fairly characteristic pattern Contrary to classic descriptions of the disease the temperature curve does not usually exhibit a remittent or undulating type of fever This may occur in the more chronic case or in infections due to *Br. melitensis* The usual course is that of an intermittent fever with diurnal variations from 98° up to 100° to 104° F Occasionally a sustained fever may take place as observed in typhoid fever The patients may feel better in the early morning hours but

Table 1 Symptomatology in 94 cases of bacteriologically proved disease due to *Br. abortus* (University of Minnesota series)

	NO OF CASES	PER CENT OF CASES
Weakness	86	91.5
Sweats	72	76.5
Chills	71	75.5
Anorexia	66	70.0

Jaundice	1	1.0
Pain over sacroiliac joint	1	1.0

as evening draws on the face may feel flushed and a rise in temperature is associated with the onset of a headache. Nights are marked by discomforting sweats and insomnia. Pain involving the muscles of the back of the neck is a common complaint. Persistent anorexia results in weight loss. Vasomotor disturbances are reflected by the presence of an intermittent tachycardia, labile blood pressure and cold and moist palms of the hands and soles of the feet. Amenorrhea may appear in young women and the sexual drive in both sexes is greatly

diminished. Nervousness is a constant feature with the display of gross tremors of the extended fingers and tongue. The patients become irritable and mentally depressed. Visual disturbances are not uncommon. Brucellosis does not cause a greater number of abortions or miscarriages in pregnancy than many other bacteremic and febrile diseases.

**Complications.** Serious complications occasionally occur and depend in part upon the species of *Brucella* causing the disease. Organic disturbance of the central nervous system may be manifested by encephalitis and meningitis which are usually chronic and are frequently associated with ocular complaints and diminution in hearing. *Peripheral neuritis* is not an uncommon complication especially in disease due to *Br. melitensis*. An excruciating type of pain over the course of the sciatic nerve either unilateral or bilateral is encountered. *Radiculoneuritis* is often associated with spondylitis. Destructive bone lesions are occasionally seen with involvement of the spine. The spondylitis of brucellosis most often involves the thoracolumbar area and is characterized by a destruction of the intervertebral disks and the adjoining vertebral bodies. Brucellosis causes a destructive suppurative arthritis usually attacking but a single joint. A deforming and chronic polyarthritis is extremely rare if it ever does occur as a complication of brucellosis. Single osteolytic lesions of the long bones occasionally appear similar to the Brodie's abscess caused by typhoid bacilli. A more serious complication is vegetative bacterial endocarditis. Pulmonary infiltration and pleural effusions have been described. Though *Brucellae* uniformly localize in the liver in bacteremic cases with the formation of granulomas, serious hepatitis is a rare complication. However there is evidence that brucellosis may at least be a participating factor in the genesis of some cases of cirrhosis of the liver. An occasional complication of brucellosis due to *Br. melitensis* is orchitis. Cystitis and nephritis have been reported as rare complications.

**Duration of Acute Illness.** In a few instances brucellosis may remain active for many years with either an intermittent or continuous state of debility. In discussing the duration of infections to *Br. melitensis* and summing up the experience of the Mediterranean Fever Commission, Eyre stated that 85 per cent of the patients had recovered within three months. Observations at the University of Minnesota Hospitals between 1937 and 1956 on cases

infected with *Br abortus* revealed that the majority of patients had recovered within three to six months and that less than 20 per cent had residuals of their disease after one year. Now that highly effective therapy has become available, the duration of the disease has been shortened considerably.

**Chronic Brucellosis** Patients with chronic brucellosis must be carefully differentiated from patients with personality aberrations or neurological disorders, especially if immunologic evidence points to past contact with *Brucella*. Acute brucellosis in most patients has a marked impact upon the central nervous system and disturbs the equilibrium of the autonomic nervous system. The main symptomatology of weakness, head aches, sweats, anorexia, constipation, insomnia, irritability, nervousness, and depression emphasizes the neurogenic features of the disease. If active disease persists for weeks, these manifestations become deeply entrenched as an emotional pattern of the patient. It is readily seen why in unstable persons or in those with an underlying psychoneurosis, brucellosis may have serious repercussions in the ensuing years. Long after the infection has subsided, a few patients flounder in a state of ill health, they and their physicians explaining this lack of well-being on the misconstrued basis of chronic brucellosis. In endemic areas, especially many persons have been exposed to brucellosis without serious consequences. A considerable number have had their tissues invaded by *Brucella* without having had any demonstrable clinical evidence of active disease. Included in this group have been those with psychoneurosis, asthenia, and anxiety states. On the basis of inconclusive laboratory and immunological data, an erroneous diagnosis of chronic brucellosis may be pinned on these emotionally disturbed people.

**Diagnosis** The diagnosis of brucellosis can be made with certainty only on the basis of laboratory procedures. Epidemiological information of a possible exposure to the disease, coupled with a symptomatology consistent with brucellosis, should lead the physician to make a presumptive diagnosis, which then should be followed up with appropriate diagnostic procedures. In a febrile patient, the leukocyte count of the peripheral blood may be helpful in the rapid detection or elimination of brucellosis. The total number of leukocytes is usually normal or reduced. It is most unusual to have a count exceeding 10,000 cells per cu mm in an uncomplicated acute case. The differential count usually shows a relative

lymphocytosis. The erythrocyte sedimentation rate may be normal or accelerated and is of no diagnostic value. It may be of some prognostic aid when the rate is rapid in the sense that a persistently abnormal value may indicate the presence of active disease. Aspirated sternal bone marrow may reveal the presence of granulomas, which are characteristic but not specific for brucellosis.

**Agglutination Reaction** The agglutination test provides a dependable laboratory method for making a diagnosis of brucellosis. Consistent success with the agglutination reaction is dependent upon a reliable antigen and upon the techniques which are used. Rapid slide agglutination tests are valuable for bedside or office use. For this purpose, Castaneda's antigen and techniques have been utilized at the University of Minnesota Hospitals. The antigen is a formalized aqueous suspension of *Brucella* cells stained with methylene blue and titrated so that positive reactions are obtained only when the peripheral blood has agglutinins in a titer of 1:100 or higher as determined by the multiple dilution tube method. In Castaneda's test, when a drop of blood from the finger is mixed with a drop of the antigen on the slide, the blue peripheral ring of agglutinated antigen may be demonstrated within thirty seconds. The multiple dilution tube method should also be used. In the laboratories of the University Hospitals and of the Minnesota State Department of Health, a satisfactory antigen has been that supplied by the United States Bureau of Animal Industry. When the agglutination test is properly performed with a sensitive antigen, agglutinins are uniformly demonstrated in acute or chronic cases of brucellosis, with but rare exceptions. Agglutinins were observed in 267 of 268 consecutive bacteriologically proved cases of brucellosis in Minnesota. Over 90 per cent of the patients exhibited titers of 1:320 or above. The higher the titer of agglutinins, the more likely that cultures of blood will be positive. At the University Hospitals, only a very rare proved case of brucellosis has failed to show agglutinins in the blood in a period of twelve years. If the titer is 1:100 or above, serious consideration must be given to the diagnosis of brucellosis. As in typhoid fever, a rising titer of agglutinins during an acute febrile illness is of considerable diagnostic importance. It is the exceptional case in which a dilution under 1:100 is a reliable index of active disease. Agglutinins may be demonstrated in the blood months and years after

patients have recovered from their illness Agglutinins for *Brucella* may be stimulated by *P. tularensis* and after vaccination for cholera with *Vibrio cholerae* A technical point to be recalled is that in the macroscopic tube method a prozone phenomenon may be present in which the lower dilutions of serum show no agglutination of the antigen Rarely a blocking of the antigen antibody reaction may occur Blocking antibodies are more likely to occur in the chronic cases

As a practical procedure there is no advantage in using the complement fixation test The opsonocytophagic test is a measure of the phagocytosis of *Brucella* by polymorphonuclear neutrophile leukocytes The test yields such meager and indecisive information in the sporadic cases of suspected brucellosis that it is not advocated as a diagnostic procedure A culture of venous blood preferably several should be undertaken in every patient suspected of having brucellosis This applies particularly to persons having a positive agglutination reaction Bacteremia is more likely to be demonstrated in febrile patients with a high titer of *Brucella* agglutinins and an enlarged and tender spleen At the University Hospitals positive blood cultures have been obtained in about 50 per cent of all the cases of brucellosis Most of these patients had infections due to *Br. abortus* In an occasional case *Brucella* may be cultured from aspirated sternal bone marrow when simultaneous cultures of venous blood remain sterile The organisms have been isolated from the bile urine and cerebrospinal fluid

**Cutaneous Tests** Intradermal reactions following the injection of *Brucella* antigens indicate a specific state of hypersensitivity to *Brucella* Like the tuberculin reaction in tuberculosis a positive *Brucella* skin test indicates past invasion of the body by organisms but it does not mean that active disease is present Intradermal tests may be performed with heat killed *Brucella* cells a nucleoprotein fraction (brucellergin) and purified protein fraction all of which yield a delayed type of reaction reaching their maximum in twenty four to forty eight hours The carbohydrate fraction of *Brucella* results in an immediate cutaneous reaction The great majority of acute and chronic cases of brucellosis demonstrate positive skin tests Exceptions include the acute cases of only a few days duration and the seriously ill patients Patients with *Brucella* subacute bacterial endocarditis have a high titer of agglutinins and nega-

tive skin tests and recovery is associated with the appearance of positive skin tests Dermal hypersensitivity may persist for years after the patient has recovered from the disease It should be emphasized that all the antigens may provoke the appearance of *Brucella* agglutinins in normal persons a week or two after an injection In these circumstances titers well over 1:100 may be achieved

The skin test is an unreliable method for detecting active cases of brucellosis and its routine use is not recommended If agglutinins are absent from the blood and blood cultures remain sterile a diagnosis of active brucellosis is not justified If in a particular case there is a history of possible exposure to the disease and the illness is consistent with the characteristic pattern of brucellosis and agglutinins are present in a titer of 1:100 or above no further information is to be gained by performing a skin test If in such a case agglutinins are consistently absent and blood cultures remain sterile a positive or negative skin test can not decide the issue

**Differential Diagnosis** In the differential diagnosis of acute brucellosis other febrile diseases must be considered Brucellosis is commonly mistaken for influenza but the latter disease is a self limited illness of short duration and may be associated with upper respiratory symptoms Infectious mononucleosis is differentiated from brucellosis on the basis of hematological and serological evidence Where malaria and brucellosis occur together the diagnosis of the former is resolved by finding plasmodia in blood films Serological and cultural studies should differentiate brucellosis from Hodgkin's disease lymphoblastoma and tuberculosis Typhoid fever is differentiated by isolating *S. typhosa* from the blood and by the agglutination test The more chronic cases of brucellosis may be differentiated only with considerable difficulty from psychoneurosis or an anxiety state Not infrequently an attack of brucellosis may be the trigger mechanism for displaying an underlying neurosis and neurotic symptoms may persist long after the infection has subsided

**Prognosis** The natural course of brucellosis will depend upon the geographical area where the disease is being observed and the species of *Brucella* causing illness In a locality where a population is malnourished and parasitized by other diseases *Br. melitensis* will cause more chronic disabling illness than in a community where good health and nutrition abound and where

brucellosis is caused by *Br abortus*. In general the case mortality rate of the disease is not greater than 2 to 3 per cent and up to 75 per cent of the patients recover within three to six months. Now that highly effective treatment is available the incidence of chronic illness should be considerably reduced. In a small number of cases a relapsing type of febrile illness is observed. Reinfections may also occur. When there is repeated exposure to the disease it is not always possible to distinguish between a relapse and a reinfection.

**Treatment General Management** It is of primary importance that the physician reassure any patient having either acute or chronic brucellosis that the disease is self limited and that he will completely recover from his illness. Too often patients are informed that brucellosis is a chronic debilitating disease for which there is no satisfactory treatment. The patient then corroborates this dismal outlook by reading about the disease and consulting with his friends and other physicians. Finally he is psychologically prepared to endure an illness of several years duration. It is easy to see why a mistaken diagnosis of chronic brucellosis in the place of a correct diagnosis of psychoneurosis provides an escape mechanism for many persons and a needless infliction for others. It cannot be emphasized too strongly that vigorous reassurance by the physician that the patient will recover from this illness is essential whether or not specific therapy is used. Another therapeutic recommendation of major value to the patient is rest, physical and mental. Since the outstanding symptoms of brucellosis are weakness and easy fatigability, the victims are unable to pursue their daily routines. Not infrequently, adequate rest is associated with a decline in temperature and permanent recovery. One need only consult the reports of the Mediterranean Fever Commission to appreciate the value of rest. Any specific therapy in brucellosis should be augmented by intelligent psychotherapy. There are few other diseases in which indecision or discouragement on the part of the physician is so detrimental to the welfare of the patient.

**Antimicrobial Therapy** Treatment with antibrucella agents is recommended for either acute or chronic cases. The tetracycline drugs have been used effectively in the treatment of both acute and chronic brucellosis. The recommended dose for each of these drugs is 0.5 gm every six hours for three to four weeks. In infections due

to *Br abortus* approximately 80 to 90 per cent have recovered after an initial course of treatment. Relapses can be treated favorably with a second or even a third course of chemotherapy. The foregoing treatment is recommended for the mildly ill patient and especially for those having disease due to *Br abortus*. For the more seriously ill patient with or without complications and particularly for those having infections caused by *Br melitensis* or *Br suis* it is recommended that tetracycline should be administered in the doses already suggested along with dihydrostreptomycin which is given intramuscularly in a dose of 2.0 gm daily. The administration of the two drugs together should be prescribed for a minimum of fourteen to twenty one days. Chloramphenicol is less effective than are tetracyclines.

**Attempts at Desensitization** It is common practice to treat the more chronic cases of brucellosis with *Brucella* antigens such as heat killed cells and filtrates (brucellin). Unless the injection of antigens is carefully controlled, disturbing local and systemic reactions may occur. Because of the dubious clinical results obtained with such a procedure and because some patients are extremely sensitive to the antigen, this type of treatment has not been advocated at the University of Minnesota Hospitals. It is more logical and practicable to use an antibrucella drug or drugs as an aid to the tissues in eradicating the organisms rather than subject patients to a prolonged period of desensitization or immunization with *Brucella* antigens.

**Prevention** Brucellosis as a human disease will be eliminated only when the reservoir in domestic animals is eradicated. There is no entirely safe method for immunizing human beings against brucellosis. A significant segment of the population may be protected against the disease by legislation requiring that all milk destined for human consumption be pasteurized.

## Pasteurella Infections

### PLAGUE

**Definition** Plague is an acute infection caused by *Pasteurella pestis* and transmitted chiefly by certain fleas. Although man is very susceptible, plague is basically a disease of rodents. It is enzootic or epizootic in many wild rodents and in domestic rats from which it spreads to man. Plague is characterized by inflammation of the lymphatic and blood vascular system and by hemorrhages in the tissues. It is customary to divide the disease into three types: bubonic, septicemic, and pneumonic. The disease, however, may be considered fundamentally a single entity. The septicemic type is characterized by wide extension and great severity. The bubonic and pneumonic types have important epidemiological and clinical significance which is discussed later.

**History** Plague constitutes the black death of history and literature (Boccaccio, *Decameron*). Epidemics swept in waves through Europe during the Middle Ages and up to the first part of the nineteenth century, often killing one in ten or more of the population. In 1894, plague began to spread from western China and in fifteen years had reached most parts of the world. It arrived in the United States in 1900. Small outbreaks of pneumonic plague occurred in California in 1919 and 1924.

**Etiology** *Pasteurella pestis* (Yersin and Kitasato, 1894) is a short, thick bacillus with rounded ends. Its form varies greatly according to the conditions in which it is obtained or grown. A capsule is demonstrable. This organism is aerobic, grows well on usual media, is nonmotile, easily stained, and gram negative. Characteristic stained preparations show a marked bipolar configuration. Under favorable conditions in darkness and moisture it may live outside the body for months or even years. The bacillus is killed by thorough drying in air for two or three days. It may remain viable in dead bodies for weeks, in flea feces for a month, and in pus or sputum for one or two weeks. *Pasteurella pestis* may survive for some time in grain, cotton, and gunny sacks. It is quickly killed by a temperature of 80°C, but is very resistant to cold, surviving almost indefinitely in frozen material.

**Distribution and Epidemiology** The principal centers of human plague are China, Burma, and India. The disease often appears in Ceylon, Indo-China, Thailand, Indonesia, the eastern and southern shores of the

Mediterranean, the Azores, and parts of Africa and South America. A few cases occur from time to time in the United States; a fatal instance of bubonic plague having been reported in California in 1956.

Many species of wild rodent are infected with plague in various parts of the world, including central and eastern Asia, Russia, South Africa, South America, Hawaii, and the United States (sylvatic plague). Ground squirrels and prairie dogs have been found infected throughout the western part of the United States.

Plague may be transmitted from wild rodent to domestic rat or vice versa from either of these to man, and from man to man. Most human infections are generally considered to be acquired from rats, especially the domestic black rat, which is now reappearing in Europe after an absence of over a century. Human cases arise, however, from various other rodents as well as the black rat, and from man himself. Plague is usually transmitted by rodent fleas, many species of which are capable of carrying the disease. In man, transmission is ordinarily through rubbing into the skin the infected vomitus or feces of a rodent flea. In addition, the human flea *Pulex irritans* is considered a potential vector, and other insects have been incriminated. Man sometimes acquires plague by contact with the bodies of rodents or human beings sick or dead of the disease, or by handling tissues, blood, or discharges derived from them. Apparently, the disease can be acquired by ingestion. Inhalation is an uncommon but extremely dangerous method of spread, since it gives rise to fulminant primary plague pneumonia. Usually, the inhaled infective material consists of droplets from the sputum of patients with plague pneumonia.

Plague is spread from place to place chiefly by migration or transportation (especially in ships) of infected rats or other rodents. It is occasionally transported by patients with mild disease and by infected fleas through their survival in grain sacks.

There is no evidence of any racial age or sex variation in susceptibility. The development of human epidemics is determined largely by the following conditions: presence of the infection in rats or other rodents; size of the rodent population; infestation of rodents with fleas; and association of man with rodents. Bad housing and bad sanitation are favorable to rats. Moisture and temperatures between 50° and 80°F are generally favorable to fleas. Human crowding and poor hygiene are important factors, especially in droplet trans-

mission which is also favored by cold temperatures

The method of transmission has great epidemiological and clinical significance. Inhalation is associated with severe pulmonary disease which is rapidly fatal. This form of the infection is called pneumonic plague. Other forms may be grouped as bubonic plague.

**Morbid Anatomy.** Rarely a pustule is found at the site of entry of the infection. The most marked changes are in and about the lymphatics and lymph nodes which are swollen, edematous and hemorrhagic. Buboes or swollen nodes may not be visible on the exterior. The characteristic processes are edema, formation of hemorrhage and necrosis. The spleen is much swollen, grayish and soft. Acute hemorrhagic nephritis and meningitis are occasionally present. Inflammation of the endothelium of lymphatics and blood vessels with small embolic lesions is characteristic. Large numbers of bacilli are often found in plague lesions and even in the blood. Plague pneumonia though it may occur in other cases is the predominant finding in the pneumonic form of the disease in which there are usually no extensive changes in other parts of the body. In this condition the lungs generally show confluent lobular consolidation but the distribution may be lobar. The appearance is one of engorgement with little accumulation of fibrin or leukocytes.

**Pathogenesis.** In mild cases the bacilli remain for the most part localized in the lymphatic system with only occasional organisms entering the blood. In severe cases they invade and multiply in the blood stream and may reach all parts of the body (septicemic plague). The formation of an exotoxin has not been demonstrated nor have the physiological and chemical changes produced by the infection been analyzed in detail. Except in very mild or extremely severe instances a leukocytosis (usually 20,000 to 25,000 per cu mm) develops, the increase being mainly in neutrophilic granulocytes. There is no anemia. The urine is scanty and usually contains albumin casts and erythrocytes. Hematuria may occur. An attack of plague usually confers immunity against subsequent infection.

**Symptoms.** The incubation period varies from two to ten days. Apart from infections acquired by inhalation the severity also varies. In mild cases with little extension of the disease there may be no constitutional symptoms and the patient may remain am-

bulant. In severe infections which spread rapidly and in pneumonic plague prostration quickly occurs. Headache, dizziness and thirst are common complaints. Many patients are confused. As a rule there is high remittent fever and marked restlessness. The respirations are fast and shallow and the pulse is rapid and feeble. In a few cases a pustule may be found at the site of inoculation. Signs of lymphangitis may be visible. Enlarged lymph nodes or buboes begin to appear on the second day. Pain in them varies from slight to severe. They are usually red and tender. At first they are hard but they generally suppurate and become soft and matted together. Buboes may rupture and discharge their contents but sometimes they resolve without so doing. The surrounding tissue is inflamed and edematous. In septicemic cases blebs, petechiae or purpuric spots may be seen in the skin. Rarely areas of skin may become necrotic. Hemorrhages may take place from the nose, the stomach and the bowel and in pneumonic cases from the lungs. In most so-called bubonic cases the lungs show little or nothing though patches of pneumonia may be present in such cases there is usually no sputum. In pneumonic plague the physical signs are usually minimal and consist mainly of scattered fine rales but breathing is rapid and shallow and cyanosis is marked. In these cases the sputum is thin at first watery and later bloody. It is loaded with bacilli. Although the spleen is usually enlarged in all types of plague it is often not palpable. At first apathetic patients tend to become delirious. Convulsions and coma may develop. A few instances of subacute meningitis have been described. The principal complications are secondary infections which often arise in buboes and in the lungs where they must be distinguished from plague pneumonia.

**Diagnosis.** The possibility of plague should be suggested by epidemiological considerations and by the clinical picture. The difficulties in differential diagnosis vary with the stage and anatomical developments. Plague buboes must be separated from adenitis due to streptococcal infections, lymphogranuloma venereum, syphilis and filariasis. Septicemic plague might be confused with many forms of septicemia, tularemia, several forms of typhus, typhoid fever and malaria. Pneumonic plague should be distinguished from streptococcal pneumonia of the type sometimes associated with influenza.

The specific diagnosis of plague is made by demonstrating the presence of *P. pestis*.

in the contents of buboes (obtained by aspiration) in blood or in sputum. All material which is considered as possibly infected with plague must be handled with the greatest care. All animals inoculated for diagnosis must be free of fleas and other ectoparasites and must be kept in insect proof cages in a room containing no other animals. Everyone who handles smears, cultures, cages or inoculated animals must wear gowns, masks and rubber gloves. Throughout all diagnostic procedures the strictest aseptic technique must be observed.

Smears should be stained with methylene blue and by Gram's method. Characteristic bacilli are usually seen in good preparations of bubo contents and in pneumonic cases in the sputum. Occasionally they are even found in blood smears. Cultures and animal inoculations are often necessary, however, and should always be made for confirmation of smear findings. The plague bacillus grows well on nutrient agar and in broth. The reaction should be approximately neutral and the incubating temperature should be below 30°C. Mice, rats and guinea pigs are used for inoculation, which is done by intraperitoneal injection or by rubbing material into the scarified skin. If plague is inoculated, these animals die in twenty-four to seventy-two hours. Characteristic lesions should be found and *P. pestis* should be recovered by culture. Agglutination reactions cannot be used.

**Prognosis.** The course is usually run in five or six days at most. In very severe cases it is over within three days. The overall fatality rate is not accurately known, because numerous mild cases are not counted. Before the use of chemotherapy, fatality rates in bubonic cases without wide extension of the disease ran from 25 to 75 per cent. Recovery was rare in severe septicemic cases and pneumonic plague was regarded as uniformly fatal. Chemotherapy greatly improves the outlook.

**Treatment.** Patients should be confined to bed and strict isolation should be maintained. Good general medical and nursing care is essential. The type of diet has little importance. The fluid intake should be such as to ensure a daily volume of urine of at least 1500 ml. Fluid including glucose solution should be given slowly by the intravenous route if necessary. Restlessness and delirium are best treated with morphine (10 mg. for adults). With the exception of antimicrobial agents, other drugs have little if any place in the treat-

ment of plague. Antiplague serum and serum globulin have been recommended but their value remains uncertain and reliable preparations are not generally available.

**Chemotherapy.** Sulfadiazine, streptomycin, chloramphenicol and oxytetracycline have all been shown to be efficacious. In one series of 118 streptomycin-treated patients only 4 died. A number of recoveries from pneumonic plague are on record. Therapy must be adjusted to the severity of the disease and to its duration. The earlier chemotherapy is begun, the better will be the results. In severe and late cases, especially in pneumonic plague, full dosage of the best available drug is needed. The relative value of the antimicrobial agents mentioned is not yet clear. For most cases, streptomycin is recommended as the first choice. It may be given intramuscularly in 0.5 gm. doses at intervals of three to six hours for twenty-four to forty-eight hours, followed by a total daily dosage of 15 to 30 gm. in divided doses for about six days in the usual case.

The suggested schedule for either chloramphenicol or the tetracyclines is three treatments at three-hour intervals of 0.5 gm. orally and 0.5 gm. intravenously followed by oral doses amounting to 40 gm. a day for two days and 20 to 30 gm. a day for four or five days. The possibilities of toxic reactions to all three drugs must be borne in mind as well as the possible development of drug-resistant organisms.

Sulfadiazine is also efficacious in less severe cases. Its use is sometimes combined with that of streptomycin. In mild or very early cases it may be given by mouth in the initial dose of 40 gm., followed by 15 to 20 gm. every four hours until the temperature is normal. After the temperature is normal, the drug should be continued in doses of 0.5 gm. every four hours for about ten days. The usual precautions in the administration of sulfadiazine should be observed, particularly the maintenance of an alkaline urine which generally requires the oral administration of 24 gm. of sodium bicarbonate with each dose of sulfadiazine.

Complicating infections which may develop especially in buboes or in the respiratory tract should be treated with an antimicrobial drug to which the infecting organisms are susceptible.

**Local Treatment.** Hot wet applications may decrease the discomfort of buboes. Incision should not be performed unless and until suppuration is clearly present.

**Prevention** Patients with plague should be isolated in separate screened rooms. When a patient with pneumonic plague is found known and suspected contacts should be isolated and their temperatures taken twice a day for one week. Attendants on patients with plague pneumonia suspected or established should wear coveralls with hoods goggles and rubber gloves. All articles contaminated by the patient or his discharges should be sterilized by boiling or autoclaving or burned. A room vacated by a plague patient and its contents should be thoroughly cleaned and dusted with DDT powder. The bodies of those who have died of the disease must be handled with strict aseptic technique.

**Immunization** Vaccination is considered to afford partial protection for six months but not longer. It is recommended only for those who must necessarily undergo serious exposure or the possibility of serious exposure. It is also used in the control of localized outbreaks of plague. For individual prophylaxis two injections (0.5 and 1.0 ml respectively) of a reliable vaccine should be given with an interval of seven days. If necessary stimulating doses of 1.0 ml may be given at intervals of four to six months.

**Rodent and Flea Control** Effective prevention of plague is achieved by adequate control of rodents especially rats. The rat population should be watched for undue increases and for the presence of infected animals. Rodents that may have plague should be handled and disposed of with great care and with particular attention to the possibility that they may harbor fleas. In endemic areas trapping surveys are regularly made. To keep down the rat population all buildings and ships should be rat proofed. Adequate protection of food supplies and garbage collections against rats is essential. Rat extermination campaigns should be conducted by trained personnel. The rat poisons now recommended are sodium fluoroacetate and Warfarin. The older poisons such as red squill and thallium sulfate may also be used. All these chemicals are dangerous to man and must be used with great care. Cyanide or carbon disulfide is used in fumigation but this process can be safely applied only by specially trained workers. Local antirrat campaigns have only brief value unless extensive rat proofing is undertaken and rat harborage is destroyed. The destruction of fleas is important especially in rat harborage. DDT is a very effective agent for

this purpose. It is applied as a powder or in solution in kerosene. Control of infected wild rodents is an important unsolved problem.

### TULAREMIA

(Plague-like Disease of Rodents, Deer Fly Fever, Tick Fever, Rabbit Fever)

**Definition** Tularemia is an infectious disease caused by *Pasteurella tularensis*. It is destructive to wild animal populations acting as a heterogeneous infection-chain involving rodents and insects. Man may enter the chain accidentally or occupationally by contaminating his hands conjunctival sac or buccal cavity with infected internal organs and body fluids of mammals, birds and insects by the bite of an infected blood-sucking fly or tick or by drinking contaminated domestic or rural water. Wild rabbits and hares have been the principal sources for the disease in man.

**Bacteriology** *Pasteurella tularensis* is extremely polymorphous. It has neither capsules nor flagella. It is non-motile and gram-negative but stains well with fuchsin or crystal violet. For routine cultures glucose cysteine blood agar is excellent. The guinea pig is used for laboratory tests and the mouse for testing specimens of sputum.

**Epidemiology** Tularemia occurs in nearly all of the United States in Canada, Alaska, Mexico and Japan. With the endemic areas in central and south Russia are apparently associated the recent geographical extensions into Norway, Sweden, Czechoslovakia, Austria, Poland and since 1946 France, Belgium and Germany. Seasonal occurrence with its peak in summer is associated with rabbit hunting and with the activity of the arthropod vectors. Human disease may appear when 10 per cent of the rodents are infected. More than 26,000 human cases have been observed since

1924 the highest annual incidence was 1 401 cases in 1947 Sex race and age are not factors in the incidence The history and epidemiology of tularemia have been reviewed by Ayres and Feemster and Foshay

*Pasteurella tularensis* requires no particular portal of entry The most important sources of human infections are (1) skinning and processing of meat and fur of wild mammals (principally cottontail and jack rabbits also muskrats beavers and pheasants) (2) arthropod bites particularly of deer flies mosquitoes and ticks or contact with their feces (e.g. in the wool of sheep) (3) ingestion of contaminated water or inadequately cooked rabbit meat (4) laboratory exposure presumably aerogenic The source of infection is not established with any degree of certainty in about half of the cases diagnosed in some regions The virulence of the invading strain seems to participate in determining the clinical form the infection takes

No proved human to human transmission of tularemia has been reported Although *P. tularensis* is easily recoverable by nasal and pharyngeal swabs or from sputum in cases of tularemic pneumonia and in many without pneumonia no secondary case has ever been recorded in bedside attendants exposed to droplet infection

**Morbid Anatomy** The autopsy reports by Foshay Lillie and Francis stress the presence of focal areas of necrosis throughout the body Macroscopically whitish yellow foci ranging in size from hardly visible to 1 cm in diameter are found in the lymph nodes spleen liver kidneys and lungs

**Symptoms** The incubation period is from one to ten days Only the typhoid type proceeds as a general disease without local processes The onset is sudden and the patient usually remembers the hour at which he fell ill Severe headache vomiting chills and fever with an initial rise in temperature above 104° F accompanied by general aching and weakness are followed by prostration sweats and loss of weight Delirium and stupor may be present in the more severe cases The constancy of the sequence of initial rise in temperature remission and secondary rise is striking in the cryptogenic type of the disease Continuous high temperature is noted in extreme toxemia Ordinarily the febrile period may last ten to fifteen days in the more severe forms the disease usually runs a course of three to four weeks Febrile periods or elevation of temperature of 1

degree may persist for three weeks Papular exanthema on the palmar surfaces or roseola pustules and petechiae on any part of the body may appear at any stage in all forms of tularemia They heal by absorption or exfoliation

Enlargement of the spleen is evident in about one quarter of the cases and is not great on rare occasions it extends from three to four fingerbreadths below the costal margin Tenderness and pain indicate the existence of a perisplenitis A slight to moderate polymorphonuclear leukocytosis (12 000 to 15 000 cells per cu mm) may be noted Anemia is common The amount of urine is diminished and results of urinalysis suggest the presence of fever Myalgia arthralgia and neuralgia occur frequently

**Cutaneous Tularemia** Thirty six to forty eight hours after the onset of the disease with slight painful enlargement of a lymph node the patient usually notices that a previous cut or sore is inflamed and tender This primary lesion evolves from a papular to a pustular stage with a necrotic plug The pustule is supplanted by a punched out ulcer with scanty serous discharge which ultimately is replaced by a scar Not infrequently painful lymphatics with or without subcutaneous nodules (nodular lymphangitis) resembling mycotic lesions extend from the ulcer to the regional epitrochlear or axillary lymph nodes The nodes vary in size from that of an almond to that of a small orange Sometimes several groups of nodes show reactions to a single primary lesion for example the axillary and supraclavicular nodes may react to a single ulcer on the shoulder Some lymph nodes suppurate in one to twenty four months and ultimately may require incision others remain hard tender and palpable for periods up to twelve months

**Ophthalmic Tularemia** The primary localization is in the conjunctival sac it occurs unilaterally or rarely bilaterally Itching lachrimation photophobia and pain are early subjective symptoms which are accompanied by swelling of the preauricular parotid submaxillary and cervical lymph nodes The eyelids are swollen and the chemotic deep red conjunctiva is studded with small discrete yellow nodules Occasionally both the palpebral and bulbar conjunctivas are covered by a gray translucent organized exudate Punched out ulcers follow the breakdown of the necrotic nodules A thin mucoid or purulent discharge accompanies the conjunctivitis for three to five weeks after which the swelling recedes and complete recovery is the rule

Suppuration of the regional lymph nodes is fairly common in ophthalmic tularemia. Dacryocystitis, corneal ulcers, permanent impairment of vision, optic atrophy and blindness have been observed following perforation of the cornea.

**Cryptogenic Tularemia** The symptoms of a general systemic infection are fever, prostration, toxemia with drowsiness or a typhoidal state, abdominal distress and prostration. Severe pulmonary symptoms in at least 50 per cent of the cases or intestinal symptoms may follow.

**Pleuropulmonary Tularemia** The symptoms of pulmonary tularemia are variable and the diagnosis without laboratory aids is difficult. The disease may begin as an inhalation infection with pulmonary symptoms or may be hematogenous, secondary to some primary focus on the skin or elsewhere. In the first group, pulmonary symptoms less abrupt than in the pneumococcal types initiate the disease, hacking, non-productive cough, dyspnea, fever, malaise and occasional chills are present. Pleuritic pains may be a dominating symptom. Milder infections simulate atypical pneumonias in which the pulmonary lesions last for a month (see Primary Atypical Pneumonia p. 132).

Primary tularemic pneumonia has been reported but conclusive proof that it occurs is lacking. Pulmonary tularemia does develop in patients with other well recognized symptoms of tularemia such as ulcers or infections of the eye. Cases of this type offer no problem in diagnosis as a rule; the sickest patients are most likely to have involvement of the lungs. Pleuritis usually is present and the development of a pale yellow, slightly cloudy pleural effusion of high specific gravity but low cell count (2000 to 5000 per cu mm) is of great diagnostic value. The pneumonic consolidation as parenchymal, confluent or lobular, bronchopneumonic infiltration consists of small patchy, later large, coalescing areas. The physical signs may vary from day to day, indicative of a migratory type of pneumonia, usually more extensive in one lung than in the other. When the process is predominantly necrotizing, gangrene, cavitation and pulmonic abscesses develop in the most severe cases. Despite large cavities of abscesses the sputum is moderate in amount, mucopurulent and rarely blood-tinged or rusty. Roentgenograms taken a few days to two weeks after onset may reveal a slowly advancing lobular type of consolidation. The mediastinal and peribronchial lymph nodes almost always are enlarged.

**Oral and Abdominal Tularemia** Ingestion of insufficiently cooked wild rabbit meat or water contaminated with *P. tularensis* may cause a violent local process in the form of a necrotizing pharyngitis or angina, abscesses on the roof of the mouth, ulcers in the pharynx and nasopharynx, fever, enlargement of the submaxillary and anterior cervical lymph nodes and in some cases conjunctivitis. Vomiting, excruciating pains in the abdominal regions and diarrhea begin either during or after the fever. The course may be fulminant; children have had convulsions, become stuporous and died in the first week of illness.

**Complications** Symptoms of general peritonitis with the findings of plastic exudate at autopsy (Francis Fulmer) and persistent ascites requiring tapping three and five months after onset have been reported. Appendicitis, diarrhea and intestinal hemorrhages may be present during the last days of illness. Occasionally pericarditis, pneumothorax, thrombosis of the veins or osteomyelitis complicates the convalescence. Meningeal or leptomeningeal localization and meningoencephalitis demonstrated by isolation of *P. tularensis* from the cerebrospinal fluid usually are fatal.

**Course and Prognosis** Many of the patients are ambulatory. In about one third of the cases recovery even without complications is slow; it confers a relative immunity. Reinfection has been reported (Green and Eigelsbach, 1950). According to Foshay, the mean duration of fever in untreated cases is twenty-six days; of the adenopathy, three to four months; and of the disease, five and one-half months. Even though clinical recovery is evident, *P. tularensis* because of its facultative intracellular parasitism may remain alive in the tissue for months, perhaps years (Blackford, Foshay and Mayer). Pulmonary tularemia has had a high fatality rate (62.5 per cent); the typhoidal, cryptogenic form has had a lower one (19 per cent) when treated with antimicrobial agents (Giddens et al., 1957). The average mortality rate for tularemia in the United States has been reported at 5.6 per cent. In Louisiana the rate dropped from 33 per cent in 1934 to 7.5 per cent in 1948 because of the use of streptomycin.

**Diagnosis** Tularemia should be considered in every doubtful case of fever or atypical pneumonia in which the patient may have been exposed by contact with some animal. The following immunological and bacteriological tests in the order mentioned are valuable diagnostic aids:

1 *Intracutaneous or percutaneous allergic skin tests* with detoxified formalin killed *P. tularensis* as antigen (Foshay) may yield positive reactions on the third day of illness. Since hypersensitiveness of the skin is a notable feature of tularemia throughout the disease this method deserves more frequent use than has been customary in the past. The inflammatory response is similar to the reaction of tuberculin and the wheal attains maximal size forty-eight hours after injection or application on the scarified skin.

2 *Agglutination and Complement Fixation Tests* Specific antibodies in the blood never appear before the tenth or twelfth day of the disease and thus the agglutination test is of little help during the first period of the disease when it is most difficult to diagnose clinically. The serum of patients with brucellosis furthermore may give positive reactions with tularemic antigens. When repeatedly applied in order to determine a rise in the titer of the agglutinins the test is valuable and irreplaceable for retrospective diagnosis.

3 *Cultures* on glucose-cysteine blood agar or thioglycolate blood agar inoculation of guinea pigs or chick embryos with blood pleural effusions and infected material or of mice with sputum during life and with blood from the heart at autopsy should be made when agglutinins are absent and the course of the disease suggests tularemia. *Pasteurella tularensis* may be isolated from the sputum of persons suffering from tularemia who manifest no frank clinical signs of pulmonary involvement. The danger to the laboratory worker who makes cultures or animal tests should be guarded against.

**Differential Diagnosis** Tularemia may masquerade in a variety of forms; the signs and symptoms are so similar to many other acute infectious diseases notably influenza, psittacosis, atypical pneumonia, undulant fever, typhoid and septicemia that differential diagnosis is difficult. The subcutaneous nodules and the enlarged lymph nodes have been erroneously attributed to sporotrichosis and at autopsy tularemia has been mistaken for tuberculosis. In any locality where the infection is prevalent among rodents the clinician must have tularemia in mind.

**Treatment** Streptomycin and dihydrostreptomycin are rapidly curative. Higher doses (2 to 4.0 gm a day) are necessary in the severe typhoidal or pleuropulmonary form than in the milder ulceroglandular or

ophthalmic form (0.5 to 1.0 gm). The effect of the drugs is most dramatic in acutely ill patients treated early in whom the disease is pursuing a stormy course. The broad spectrum antimicrobials are also effective but less so than streptomycin. The tetracyclines or chloramphenicol given orally in an initial dose of 25 mg per kg of body weight followed by doses of 0.5 to 0.75 gm every six to eight hours have been recommended. The appearance of drug resistant mutants of *P. tularensis* in human beings has not been recorded and any of the drugs is effective in controlling relapses. As a rule no benefit is derived from antimicrobial therapy for longer than ten to twelve days. The local cutaneous lesions should not be incised; they are best treated by hot moist applications containing some germicide which makes the handling of the dressings less dangerous. Suppurating lymph nodes should be incised only after they show definite fluctuations. Since febrile reactions and even chills may follow such a procedure surgical treatment of tularemia should be judicious.

**Prevention** Tularemia as an everlasting enzootic and frequently epizootic disease of rodents and with a latent parasitism in insects cannot be eradicated. There is a likelihood that an effective immunizing antigen may be prepared. Until the prophylactic value of vaccine has been established it is imperative that sportsmen, butchers and those who live in regions where the infection prevails should be educated to the dangers of this disease. Rubber gloves should be worn while dressing wild rabbits. Laboratory workers should use face masks. To render the meat of rabbits harmless thorough cooking is imperative. Some reduction in the incidence of tularemia would be accomplished by supervision of interstate shipments of wild hares and of their sale for food in markets and restaurants.

## Glanders

(Farcy Morle Rotz Malleus Hautwurm)

**Definition** Glanders an acute infectious disease of horses mules and donkeys occasionally transmitted to man through discharges from the skin eyes respiratory or digestive tract is caused by *Malleomyces mallei*. It is characterized by nodules in the internal organs and by ulcerative papules or nodes of the skin and subcutaneous tissues and of the respiratory mucous membrane.

**Epidemiology** Suppressive measures have almost freed the United States and Canada from equine glanders since 1936 only twelve cases have been reported from the United States. It is seen in grooms coachmen veterinarians soldiers farmers and the like. Several cases in laboratory workers and instances of human to human transmission have been reported.

**Etiology** In smears prepared from the viscid pus of the abscesses *Malleomyces mallei* is seen usually in small numbers within and between cells as a straight or slightly curved rod 1.5 to 50  $\mu$  long and 0.5 to 0.8  $\mu$  broad singly sometimes in pairs or parallel bundles. It is nonmotile noncapsulated gram negative and stains distinctly with alkaline methylene blue or carbolthionin exhibiting a characteristic beaded granular or bipolar appearance. Cultivation may be difficult because the organism adapts itself slowly to artificial media. Virulence for different animals is variable. The hamster is the most susceptible but for diagnostic tests the guinea pig is most suitable. After intraperitoneal or even subcutaneous injection *Malleomyces mallei* localizes in the serosa covering the tunica vaginalis and incites a purulent exudate and swelling of the testes by the second to twelfth days. This testicular reaction first described by I. Strauss in 1889 is diagnostically significant provided that the exudate is examined both microscopically and culturally.

**Clinical Manifestations** *Acute Glanders* After the usual incubation time of three to five days there are general malaise headache anorexia chills temperature up to 104° F vomiting and myalgia. There are local swelling and infiltration at the site of the cutaneous infection ulcers with irregular edges and sloughing and multiple intramuscular and subcutaneous nodules along the lymphatics—the so called farcy buds—which gradually transform into ab-

scesses. They show little tendency to heal. When the primary lesions are in the nose the sticky blood tinged secretions become ropy and this material excoriates the skin and mucous membrane of the mouth tonsils throat larynx and trachea over which it runs. General infection accompanied by an exanthematous eruption delirium and coma may lead to fatal termination in two to three weeks owing to circulatory collapse. Few patients recover from acute glanders.

**Chronic Glanders** Negligible constitutional symptoms without fever may begin first general malaise and pains in the extremities are common. Within one to four weeks irregular fever tends to assume a septic character. Subcutaneous or intramuscular abscesses appear on the upper and lower extremities. When the infection localizes in the periarticular tissues the joints may be involved. Partial healing and apparent quiescence may be followed by recurrence of symptoms abscess formation pulmonary consolidation pleural disturbances and emaciation. This peculiar remittent disease may drag on for years. The lesions may heal slowly or a remission with rapid generalization may be fatal. Many patients succumb to cachexia and amyloid disease. Chronic glanders may be latent throughout its entire course. An estimated 30 to 50 per cent of the patients survive chronic glanders without treatment.

**Diagnosis** The clinical picture is not pathognomonic. Any wound infection in a person who has been in contact with horses or with a laboratory handling *Malleomyces mallei* should be regarded as gravely suspicious and culture and inoculation of hamsters should be instituted.

Complement fixation and agglutination tests in acute glanders and the diagnostic intradermal test with commercial mallein (0.1 ml of a 1:100,000 dilution) are indispensable in chronic glanders.

**Treatment** The patient must be isolated and the discharges carefully disinfected with hypochlorite or benzalkonium chloride (Roccal). Aside from symptomatic treatment chemotherapy with sulfonamides penicillin or streptomycin in the few patients treated has yielded promising results.

## MELIOIDOSIS

Until quite recently a rare specific glanders like infection melioidosis—as a rule with a septicemic course caused by *Malleomyces pseudomallei* (*Pfeifferella whitmorei*)—was believed to be confined to southeast Asia Guam and Madagascar. But two cases of chronic melioidosis have

been discovered in persons known never to have been outside the Western Hemisphere. Human to human transmission is unknown. Rats are suspected primary reservoirs but guinea pigs, cats, dogs, pigs, cattle, goats and sheep have been found infected. According to Chambon, isolation of the organism from soil and mud from marshes and ricefields in Cambodia and Vietnam probably explains the epidemiology of human melioidosis more adequately than does ingestion of food contaminated with infected rat excreta. Morphologically in stained preparations *Malleomyces pseudomallei* resembles the organism causing glanders and produces a Strauss reaction but it is actively motile, liquefies gelatin, forms corrugated colonies, attacks a wider range of carbohydrates and is as a rule highly virulent for laboratory animals and serologically distinct from *Malleomyces mallei*. The inexperienced may confuse it with *Pseudomonas aeruginosa*. The disease has developed as an acute pulmonary infection followed by hematogenous dissemination to several visceral abscesses, septicemia and death within a few days. Only 10 per cent of the cases have been diagnosed during the patients' life. Patients from endemic regions who have recovered from the acute phase may be discovered in the Western Hemisphere with febrile suppurations in diverse localizations. Isolation of the organism leads to the diagnosis of the illness known to extend its course interrupted by afebrile periods and without constitutional symptoms for up to eight years. Intensive chemotherapy with sulfonamides and penicillin in very large doses has in a few cases favorably influenced its course.

## Anthrax

(Charbon, *Maladie Charbonneuse*, Milbrandt, *Malignant Pustule* or *Cutaneous Anthrax*, *Woolsorters Disease*, Rag Pickers Disease or *Pulmonary Anthrax*)

**Definition.** Anthrax, an acute infection caused by *Bacillus anthracis*, attacks many species of animals, in particular herbivora and is transmissible from them to man. Clinically it may be an external (malignant pustule and malignant edema) or internal (pulmonary and rarely intestinal) disease.

**History.** Anthrax has been known from antiquity; the name is derived from the Latin *anthrax*, a carbuncle. Maret (1752) and Fournier (1768) defined the clinical malignant pustule in man. Chabert (1780) described anthrax in animals and Barthélemy (1823) proved its transmissibility by inoculation. Subsequently Davine (1863-1864) showed that anthrax is caused by a living organism that multiplies in the body, invades the blood stream and produces death by septicemia. He found the same organism in the malignant pustule, establishing the etiology of the disease in man and animals. Final proof of the causative role of *Bacillus anthracis* was furnished when R. Koch (1877) described the formation of spores, cultivation of the organism *in vitro*, reproduction of the disease by injection of pure cultures and recovery of the bacillus at autopsy. The study of anthrax established for the first time the specific relationship of a microbe to an infectious disease.

**Etiology.** *Bacillus anthracis*, so designated by Ferdinand Cohn (1875) and by many claimed as the cornerstone in modern bacteriology, is a nonmotile, gram positive rod which forms capsules in the tissues of man and animals. Under conditions of unfavorable growth outside the body it forms ellipsoid or oval spores quite resistant to heat (ten minutes boiling) and to chemical disinfectants. The chief criteria for identification of *B. anthracis* virulent for mice or guinea pigs and for its differentiation from *B. cereus* are lack of motility, inability to ferment salicin, feeble hemolysis, reduction of methylene blue, peptonization of milk, failure to multiply at 45° C or on agar containing 10 units of penicillin per ml, formation of smooth mucoid colonies containing capsulated bacilli grown on sealed plates of bicarbonate medium and susceptibility to specific phage action (Burdon 1956). The capsular antigens consisting of polyglutamic acids are aggregating. In combination with soluble somatic polysaccharide they incite protection and protective antibodies. An extracellular toxin produced *in vivo* and *in vitro* causes edema.

secondary shock and death in the experimental host a syndrome identical with that in natural anthrax (Smith and others 1955). Apparently no conventional antigen antibody protection is involved in acquired resistance to anthrax.

**Epidemiology** Man contracts anthrax through direct or indirect exposure to animals or animal products rarely is it spread from animal to animal. Infection occurs primarily or secondarily from feeding on contaminated pasture in low lying marshy areas or on artificial foodstuffs such as bone blood fish and maize meal. In 1951 raw bone meal imported through Belgium from Asia and southern Europe was responsible for numerous outbreaks of anthrax in swine. Sun-dried bone has caused at least twenty cases of anthrax in man in England. Anthrax spores have been found widely distributed throughout a factory using goat hair in the manufacture of interlining for men's coats. But despite recovery of virulent *B. anthracis* from air samples and dust collected from machinery walls floors clothing and body surface of workers pulmonary anthrax is rare. A relatively high but variable natural resistance is probably responsible for the low annual incidence despite probable widespread dissemination of spores in factories handling infected hair or wool.

Anthrax infection exists in a few fairly well defined districts in the United States: (1) southeastern South Dakota, northeastern Nebraska, southern California and New York; (2) the delta regions of the lower Mississippi Valley with extensions downstream from areas with favorable neutral or alkaline soil (Stein and Van Ness 1956); and (3) a belt along the Texas gulf coast. Occasional serious outbreaks occur but the incidence is kept down by preventive measures. The disease causes major epizootics throughout the world particularly in Asia, Africa and southern Europe.

*Anthrax in man* may be divided into two epidemiological groups: agricultural and industrial. *Agricultural anthrax* is usually acquired while handling skinning or autopsying infected animals. Farmers, butchers, sheep herders and veterinarians are the usual victims. The death rate unfortunately continues high because diagnosis and treatment are delayed. The lesion takes the form of a malignant pustule. *Industrial anthrax* arises from handling wool or animal hair, hides or skins and may take the form of cutaneous or pulmonary anthrax. It has recently increased in New England and the Middle Atlantic states owing to the

handling of imported infected hair, wool, carpet wool and goat hair and skins from Asia and North Africa where organization of the livestock industry is primitive (Wolff and Heimann 1951, Steele).

Over 95 per cent of the cases of human anthrax in the United States are cutaneous. These have been caused by contact with horsehair shaving brushes with anthrax meningitis as a frequent complication. Pulmonary infection was commoner than malignant pustule fifty years ago but thanks to improvements in industrial hygiene legislation and the introduction of exhaust ventilation, dust masks and proper clothing this type is now infrequent.

From 1944 to 1957 (first six months) 611 cases of human anthrax occurred in the United States. The highest incidence was in 1947 with 69 cases, 75 per cent in seven northeastern states where industrial exposure is the usual source of infection. In the remaining forty-one states agricultural exposure involved farmers and veterinarians. There are no recent records of human anthrax caused by ingestion of contaminated milk or meat. In one series of 117 cases observed between 1933 and 1955 only one pulmonary infection was diagnosed (Gold 1955). The loss due to animal anthrax during 1951-1953 in 2,360 outbreaks has been estimated at 2,988 cattle, 314 sheep, 670 horses and mules, 13 deer, 860 mink and 2 dogs.

The infection chain animal-man is as a rule broken. In 1948 however a man-to-man transmission was proved (Reilly and Beeson). Healthy persons may carry spores in their clothing.

**Symptomatology** *External Anthrax* **MALIGNANT PUSTULE** The most common form (95 per cent) of cutaneous anthrax is seen by the physician when the carbuncle has already developed. From one to three days after infection a reddened area of the skin on the arm, neck or face shows a fleabite-like patch transformed into a painless and insensible papule. Intense itching accompanies this primary lesion in its progress to a vesicle with a hard dark purplish black center. Interestingly the site of the lesions varies with the nature of the industry. Hide porters are frequently infected on the back of the neck which is more open than other parts to excoriation. In butchers and veterinarians who handle carcasses the arms or hands are affected. As a rule there is only one focus but scratching may lead to autoinfection and formation of several papules and vesicles with yellowish or hemorrhagic or even puru-

lent content. Within a few hours after the papules appear adjacent soft tissues become infiltrated and swollen. Coagulation necrosis, desiccation or scratching produces a dark bluish red tough leathery eschar which extends both in depth and width and forms with the densely edematous ring studded with small vesicles the characteristic carbuncle. The term "pustule" is unfortunate for pus does not form. Massive infiltration joins extensive hemorrhagic edema which may extend along the neck to the face or chest or even to the abdomen and lead to extraordinary distortion of the involved parts. Reddened lymphatics spread from the carbuncle to the regional lymph nodes which are painful, swollen and some times covered by an area of reddened and inflamed skin. In the mildest form with but little swelling the primary papule vesiculates rapidly and the resulting scab separates in a few days. Recovery in more severe cases is indicated by the gradually sloughing suppuration of the eschar at the end of the first week, recession of the edema and slow healing of the extensive defect by granulation leaving a disfiguring scar.

Quite early headache, joint pains, nausea, malaise and fever may accompany development of the carbuncle. The temperature varies in most cases; it is elevated but it may be normal or even subnormal. The leukocyte count may show a slight increase (10,000 to 13,000 cells per cu mm) or leukopenia with 60 to 85 per cent polymorphonuclear leukocytes. Despite the alarming aspect of the carbuncle the general manifestations of illness may be exceedingly slight. On the other hand even the early stages of the local process may be accompanied by profound malaise, vomiting, circulatory collapse, cyanosis, profuse perspiration, diarrhea and subnormal temperatures. Death may take place in three to five days. Blood cultures usually reveal anthrax bacilli.

The presence of bacilli in the blood stream does not always constitute an unfavorable prognosis. In fact the mode of action of the anthrax bacilli is by no means clearly understood. The invasion in the blood stream occurs late, remains confined to the blood vessels of the liver, lung, spleen and kidney and is accompanied by severe toxic manifestations. Embolic bacillary occlusions of the capillaries and the formation of poisons in the extravasations of blood into the organs may be principally responsible for the severe symptoms and deaths. According to Szendey, cerebral hemorrhage is present in at least 40 per cent

of the fatal cases. Cyanosis and respiratory distress are always grave symptoms.

**MALIGNANT ANTHRAX EDEMA.** This is observed in the loose connective tissue of the eyelid, hand, neck, thigh and mucous membranes. It is characterized by a doughy, soft, transparent, faintly reddish or anemic infiltration and swelling without papules and vesicles following rather than preceding constitutional symptoms. Rarely circumscribed it spreads rapidly and is apt to terminate in extensive sloughing and gangrene. In general the outcome of the edematous form is less favorable than that of the carbuncle.

**Internal Anthrax PULMONARY ANTHRAX.** This presents no characteristic clinical symptoms. The onset is sudden with rigor and fever, slight or excessive. Aside from general malaise, headache and circulatory disturbance the patients may complain of a feeling of tightness in the chest and difficulty in breathing which in some may be accelerated to 40 to 50 respirations a minute. The sensorium is usually clear. The auscultating signs are usually those of bronchitis. The mucosa of the nose, larynx and pharynx becomes reddened and swollen. With increasing dyspnea, cough and pain in the chest, pneumonic infiltrations or even pleuritic exudates become discernible. Anthrax bacilli may be demonstrated in the frothy, occasionally blood-tinged sputum. Death may occur within eighteen to forty-eight hours when the disease lasts longer (up to ten days) delirium and unconsciousness govern the clinical picture. On the other hand, absence of the severe symptoms usually accompanying acute infections and the rapidity with which collapse sets in are characteristic of this form. The disease is often suspected because the patient's occupation subjects him to inhalation of dust from hairs soiled with spores.

**GASTROINTESTINAL ANTHRAX.** This form is rare in the United States but frequent in Indonesia and southeast Asia may result from ingestion of infected food or may follow the external type when the organisms are carried to the mouth from external lesions. It may be secondary to anthrax elsewhere in the body. It may be symptomless as in Sinai's 38 patients who had eaten inadequately cooked meat from an infected calf. Or as in Soloweff's thirty cases traced to infected sausage the symptoms may include persistent vomiting, constipation and rarely diarrhea, an almost empty gastrointestinal tract with the occasional discharge of blood-tinged fecal material or pure blood.

abdominal distention and tenderness peritonitis and accumulation of exudates and relatively little fever (maximal elevation 102.2° F). His patients were restless anxiety ridden and much concerned about their illness. Collapse cyanosis and apoplectic death terminated most infections within one to three days one patient died in eleven days. At autopsy localized phlegmonous hemorrhagic infiltrations and carbuncles were noted in the ileum and cecum and hemorrhages in the myocardium and brain.

**Diagnosis** The diagnosis is greatly facilitated when the cutaneous lesions are characteristic and when the anamnesis and occupation of the patient suggest this infection. If no information is available differential diagnosis between anthrax carbuncle and simple coccal infections requires laboratory assistance. Any physician with a microscope of medium power and certain staining reagents can make an early diagnosis and thus reduce the risks. If a vesicle has formed films are made from the serum and stained. If it is already broken gentle scraping of the pimple or puncture of the eschar will produce serum rich in typical encapsulated bacilli when stained with a polychrome eosin methylene blue stain (Wright or Giemsa). Their direct cultivation on peptone agar should always be attempted. If the specimen has to be shipped the tissue serum should be dried on silk threads or a sterile glass slide. On occasion both the smear and the culture may show few or no anthrax bacilli while cocci may grow in the culture. Repeated examinations and cultures are therefore indicated. In view of the occurrence of anthrax like ba-

cilli on the skin it is imperative that diagnoses be confirmed by animal inoculations preferably in guinea pigs or mice. In pulmonary anthrax the bacillus has been found microscopically in the sputum and in the pleural exudate. Vomitus should be inspected when gastrointestinal anthrax is suspected.

Terminally and sometimes when severe general symptoms are present the bacillus may be cultivated from blood if not less than 20 ml are taken. Even in nonfatal cases and in the absence of symptoms indicative of generalization the anthrax bacillus may be isolated from the blood. Blood or cerebrospinal fluid after it has been treated with 3 per cent acetic acid solution may be centrifuged and the sediment stained with Wright's stain and examined for bacilli.

**Prognosis** The prognosis in external cutaneous anthrax is favorable provided the pustule is not on the neck or face and has not been irritated by physical and chemical procedures. Moreover if the nature of the pustule is correctly and promptly diagnosed the patient placed in bed and specific treatment instituted not later than the third day the chances for recovery in most infections are favorable. To be sure the statistics amply attest to the uneventful recovery without complications or sequelae without specific treatment. Individual susceptibility to anthrax varies considerably cutaneous even visceral infections are not as deadly as popular belief would indicate. Thompson reports that only one of twenty veterinarians (18 with malignant pustule one throat infection and one generalized

symptoms in the hand (2) a diffuse generalized skin eruption with arthritic and constitutional symptoms and negative blood culture and (3) septicemia with or without cutaneous lesions. The reddish blue swelling with raised edges well demarcated or slowly advancing and a sensation of tightness with burning or itching pain in the inflamed area are characteristic appearing one to seven days after injury. Stiffness and pain in the interphalangeal joints are common. In the rare generalized form purpuric eruptions develop remote from the primary portal of infection. The diagnosis offers no difficulties in view of the history and absence of fever. It can be confirmed by culture of biopsy material. Penicillin is the drug of choice for treatment.

## Mycobacterial Infections

### TUBERCULOSIS

**Definition.** Tuberculosis is an infectious disease caused by *Mycobacterium tuberculosis*. The disease is widespread among men and animals uniformly fatal in some species seldom if ever in others acute and generalized in some persons chronic and localized in others. Pathologically the disease is characterized by inflammatory infiltrations, tubercles, caseous necrosis, abscesses, fibrosis and calcification.

**History.** Archeological discovery of skeletons bearing the marks of tuberculous lesions indicate that the disease was present in remote antiquity. In the earliest medical records it was called consumption or phthisis because of its most conspicuous external feature, wasting. Long considered to be of many varieties and origins, the unity of the disease was first recognized by Laennec. The correctness of his conceptions was not universally acknowledged until Koch in 1882 isolated the specific organism and reproduced the disease experimentally. The avian form of bacillus was isolated in 1890 by Maffucci and the bovine form in 1898 by Theobald Smith. Within a few years after 1895 when Roentgen announced his discovery, the adaptation of roentgenography to the study of anatomical changes caused by tuberculosis added an understanding of the disease which today is indispensable in clinical practice. Finally in 1944 the discovery by Waksman and his co-workers of a practical and highly specific antibiotic led the way in a new attack

against the disease, the success of which has far exceeded anything previously attempted or done.

**Distribution.** Under certain conditions fish, reptiles, amphibians, fowls and mammals may acquire tuberculosis although in their wild state these classes are not very susceptible. Animals in captivity sometimes fall easy prey to the disease. Among domesticated animals it occurs in cattle, swine and gallinaceous birds and is seldom observed in dogs, horses and goats. In the United States and some other countries, an active plan of eradication of tuberculosis from cattle has been highly successful. In still others, the prevalence of infection among bovine herds is estimated to be as high as 40 per cent.

**Incidence in Man.** No branch of the human race has escaped the touch of tuberculosis. The severity of its effects, however, varies greatly in different communities. Although the infection is common, most people survive. The occurrence of infection, mortality and morbidity therefore must be analyzed separately. Formerly in most communities almost all adults reacted to the tuberculin test and this is still true in some sections. With few exceptions, the results of tuberculin testing provide a reliable measure of the existence and rate of occurrence of tuberculous infection in populations. On the basis of such information, the National Tuberculosis Association in 1957 estimated that approximately 55,000,000 people in the United States had already been infected. Similar evidence, however, indicates that the time of infection is being progressively postponed to the ages beyond adolescence. Tuberculin testing (patch test) of children aged thirteen to fifteen years in secondary schools of New York City in 1956 revealed only 6.9 per cent of 54,373 to be positive reactors. Among large groups of recruits of the United States Navy aged seventeen through twenty years, 4.6 per cent in 1954 were reported to have reacted to the Mantoux tuberculin test. Usually in communities with relatively high rates of death from tuberculosis, the rate of infection among youths is also relatively high. In Paris in 1952-1953, 50 per cent of the children aged fourteen were estimated to be infected (Lotte). In Japan in 1953, the percentage of reactors in this age group was 65 to 80 (Japan Anti-Tuberculosis Association). Most surveys indicate that the rate of infection is greater among males, especially after the age of adolescence. This is thought to be due to their wider peregrinations leading to more frequent contacts with sources of infection.

infection) died. The general fatality rate is around 20 per cent (Holland and the United States) but may be as high as 40 per cent. There is generally a low fatality rate for tannery anthrax but a high rate for that resulting from animal contact. Septicemia with and without involvement of the viscera and sometimes meningitis are serious complications. Double and multiple infections occur at times and recurrences are possible though not usual. When the eruption assumes the form of anthrax edema indications of diminished resistance are obvious and the outcome may be in doubt. In respiratory and alimentary anthrax the prognosis is grave largely because of the extensive visceral destruction and the presence of bacteremia (up to 300 to 400 bacilli per ml). The presence of bacilli in the blood culture justifies an unfavorable prognosis although dramatic cures may be achieved by modern therapeutic procedures. The true nature of mild cases may occasionally be suspected but is rarely proved. An attack of the disease if it produces immunity induces a resistance of only short duration. Second attacks of cutaneous anthrax have occurred within a year.

The average hospital stay is about two weeks and provided the ulcer heals in two weeks the patient returns to work within five to six weeks.

**Treatment.** The drug of choice is penicillin in daily doses of from 100 000 to 600 000 units for two to seven days. The excellent clinical response to broad spectrum antimicrobial drugs is lower and positive cultures are obtainable longer than when treatment with penicillin is instituted as soon as anthrax is diagnosed. Local edema and erythema disappear within twenty-four to forty-eight hours; pain and tenderness of the lymph nodes and all signs of systemic reaction subside rather promptly. The advantages of oral administration make the tetracycline compounds particularly useful in the treatment of ambulatory patients. European clinicians recommend combined serum penicillin therapy in grave internal anthrax.

**Prevention.** Prevention of the infection in man must first be directed to its suppression in animals by veterinary control measures. The proposals by the U. S. Public Health Service include annual vaccination of animals with a standardized potent spore vaccine or the recently developed alum precipitated protective antigen. This also prevents the disease from being a major agricultural economic problem. Sterilization

of contaminated bone meal readily accomplished is part of federal and other public health control programs. Tanneries and processing plants for animal hair and wool have tried diverse methods of sterilization but have found procedures effective in eradicating the anthrax spores from contaminated animal hides and hair unacceptable. Heating or chemical sterilization alter the physical properties of the products and render them valueless. Workers in tanneries and wool factories may be protected by rubber gloves and aprons and proper ventilation to carry off the infective dust. Ultimately prevention in some cases becomes a problem of active immunization. The Pasteurian living attenuated spore vaccine was never applicable to man and heat-killed vaccines have afforded inadequate protection. Wright has grown a nonproteolytic mutant in a chemically defined non-protein medium and has developed a sterile nontoxic product which effectively immunizes test animals. This antigen has been used on employees of woolen mills in Pennsylvania and in England but reports on its effectiveness are not yet available.

### Erysipeloid of Rosenbach

Since characterization of swine erysipelas and isolation of its causative agent *Erysipelothrix rhusiopathiae* in the United States in 1921 attention has been called to human infections. Essentially an infector of swine and poultry the organism is widely distributed in nature on putrefying animal and vegetable matter and on the slime of fish during the warm weather. Only a few human infections are attributable to contact with animals; most are occupational and are due to abrasion of the skin among fish workers, slaughtermen, butchers, cooks and housewives. Three clinical forms have been described: (1) a mild localized skin eruption accompanied by mild arthritic

studied the chemistry of the bacillus which is made up mainly of lipids waxes poly saccharides and proteins There is no capsule Though the organism is tenacious of life and may survive many months in the dark or when refrigerated it does not live long when exposed in rooms well supplied with unfiltered daylight (C R Smith) and it is killed by boiling in water for two minutes or pasteurization at 60 C

**Resistance** Man is relatively resistant to tuberculosis Infection is common but less than 10 per cent of all those infected die of the disease This bespeaks a native resistance which as a rule is highly effective Its precise nature is not understood and it cannot be clearly distinguished from the numerous other factors which influence the course of the infection Natural resistance varies with age Young infants may go on to acquire generalized tuberculosis soon after the first infection and the case fatality rate at this time of life is relatively high The mortality rate is generally low between the age of five and adolescence when there is a rise reaching its peak in females in the early twenties and somewhat later in males This suggests strongly that biological influences associated with puberty alter natural resistance The relatively high death rate in old men as compared with old women may involve similar forces

**Allergy and Immunity** These factors which begin to assert themselves shortly after the development of the first lesion modify subsequent reactions Koch demonstrated that a guinea pig infected with tubercle bacilli slowly suffers an indolent and sometimes ulcerating lesion at the site of inoculation and dies with progressive and generalized tuberculosis after a lapse of several months Within a few weeks after the inoculation the tissues for the first time become sensitive to tuberculin This altered reaction is known as tissue hypersensitivity a form of allergy Similarly Koch found that a second inoculation of bacilli into the skin of a previously infected animal produces a lesion which behaves differently from the primary The local reaction is rapid and intense with a tendency to abscess formation ulceration extrusion of the necrotic matter and subsequent healing Dissemination of bacilli from this focus through the lymph and blood streams is much slower and less severe Thus the Koch phenomenon is a manifestation of allergy and of acquired relative immunity the nature of which has been identified only partly Weakly concentrated humoral antibodies may be demonstrated More impor-

tant however as shown by Lurie is the accelerated mobilization of phagocytic cells at the site of infection these may form an effective barrier against further invasion If the primary infection was not overwhelming or was accomplished with an attenuated strain of bacilli the animal now may survive the effects of reinfection for many months In the human being tissue hypersensitivity which usually develops within five or six weeks after the first infection helps to explain certain intense inflammatory reactions such as serous pleurisy Acquired immunity which is never absolute seems to develop much more slowly and in man may not reach its height for a year or more Allergy as indicated by the intensity of the reaction to tuberculin is not a measure of immunity but most workers believe that the two are closely associated

**Heredity** The superior resistance of certain groups such as Jewish people from certain geographical areas suggests that hundreds of years of experience with tuberculosis results in the elimination of the susceptible and the survival of relatively resistant members It has been intimated that specific immunity may be inherited to a degree but this has never been proved The evidence is more suggestive that some racial stocks have a stronger or weaker natural resistance—a genetic character

**Constitution and Race** Clinicians have often described types of people thought to be susceptible to tuberculosis e.g. the asthenic thin skinned slender haired titian blond However precise identification of the nature of constitutional factors remains for the future Kallmann and Reisner studying monozygotic and dizygotic pairs of twins found that the chance of developing tuberculosis increases in direct proportion to the degree of genetic relationship to a tuberculous person Lurie has been able to breed families of rabbits in which the greatly varying resistance is a function of their genetic constitution The higher mortality among Negroes in many parts of the world is attributed in some degree to poor living conditions However the striking tendency of the lesions to undergo caseation rapidly and the frequency of generalized dissemination of the infection indicate that there is a real constitutional peculiarity in this race In the United States the tuberculosis death rate for nonwhite persons is about three times that among white people in 1910 11 per cent of all deaths from tuberculosis occurred in nonwhite people while in 1954 the proportion was 26 per cent The disease

Medlar in 1947 after an extensive study of necropsy material in New York City reported that evidence of tuberculous infection was present in approximately 35 per cent of persons ten to nineteen years old at the time of death. The incidence of infection rose to about 65 per cent in the thirty to thirty-nine years age group and to 85 per cent or more in the group above the age of sixty years. His comparative study of 17 196 necropsy protocols led him to conclude that the incidence of tuberculous lesions was approximately the same in 1940 to 1945 as it was in 1916 to 1920 in striking contrast to the steady diminution of deaths due directly to the disease. It may be inferred therefore that infection is still widely prevalent but that the infected persons better resist the invasive effects of the resulting lesions. The increase of relatively resistant persons is presumably a result of the improvement in living conditions nutrition and other hygienic standards.

**Mortality** from tuberculosis also varies greatly in different localities. It is estimated that it causes several million deaths in the world each year. Areas with high rates include eastern Europe, Asia, Latin America, Alaska, Greenland, Newfoundland and Labrador. Differences in the number of deaths from the disease per 100 000 population are exemplified by the following percentages reported for the year 1956: Chile 63.1, Finland 38.1, France 28.6, Switzerland 18.4, England and Wales 12, Sweden 9.8, Canada 7.8, Israel 6.1, Netherlands 5.4.\* For many decades the rates in many nations have declined steadily, exceptions being noted in temporary upward trends during great wars. The decline was sharply accelerated about 1947-1948 when specific chemotherapy became available.

In the United States the rate per 100 000 per year declined from 202 in 1900 to 113.1 in 1920, 45 in 1940 and to 3 (provisional) in 1956. The most striking reductions have occurred in the early decades of life (Fig. 28). In this country tuberculosis now stands thirteenth among the leading causes of death. In 1956 it was responsible for one in every 113 deaths compared with one in 43 in 1950. Death is due to the pulmonary form of the disease in about 92 per cent of all cases and to nonpulmonary or generalized forms in 8 per cent. In 1956 there were 13 927 (estimated) deaths from tuberculosis in the United States. Four to six new active cases are reported each year for every death. The National Tuberculosis

Association estimates that in 1956 there were 250 000 active cases in the United States.

**Epidemiology.** As man may be infected by human or bovine tubercle bacilli, the source is usually traced to another person with tuberculosis or to a tuberculous cow. Contaminated milk is seldom implicated in this country but elsewhere it is considered responsible for about 10 per cent of the cases of the disease among humans. Much more often however human infection is the result of inhaling air contaminated by the person with "open" (i.e. cavitory) pulmonary tuberculosis as he coughs, sneezes and expectorates heedless of hygienic care. Other lesions such as superficial tuberculous sinuses may constitute sources and the possibility of transmission through contaminated urine or feces occasionally has to be considered. Direct mouth-to-mouth transmission may occur particularly in nurslings. As would be expected therefore many new cases of tuberculosis are discovered near the abodes of people previously afflicted. In this sense the disease is frequently familial or household and it is also somewhat more prevalent among the personnel of hospitals or other institutions caring for tuberculous patients. Infection has been shown to be almost inevitable among young children who in the home have close contact with the "open" case, usually in an adult. Infrequently infection occurs through the broken skin, e.g. among laboratory workers handling fresh tuberculous specimens. Rarely a fetus is infected by way of the blood stream from a tuberculous placenta or less often by aspiration of bacilliferous amniotic fluid into the lungs.

**Bacteriology.** Three varieties of tubercle bacilli have been known longest and best: *Mycobacterium tuberculosis* var. *hominis*, *M. tuberculosis* var. *bovis* and *M. avium*. Man may be infected by the human or bovine varieties seldom by the avian. Lower animals are infected most often by the bovine variant. This varying pathogenicity may be used to help identify the variety involved. Thus guinea pigs are susceptible to infection by bovine and human bacilli but not the avian; rabbits are susceptible to the bovine and avian much less to human; fowls usually are susceptible only to the avian. The bacillus is a rod-shaped organism distinguished particularly by its acid fastness to stains. Granular forms have been described but these may be artefacts (Yegian and Porter). The bacillus grows slowly and aerobically on various culture media. R. J. Anderson particularly has

\* Compiled by Statistical Division, New York Tuberculosis and Health Association.

may follow soon after caseation. The liquid collection is prone to break its bounds. In the lungs it frequently sloughs and empties its contents into the bronchus. A renal focus empties into the ureter. A necrotic superficial lymph node commonly sloughs through the skin or if the node is deeply situated may discharge into the trachea or some other passage. A vertebral abscess may dissect its way within the psoas sheath and rupture the skin of the groin. Whatever the outlet sloughing and evacuation are accomplished not primarily by the mechanical disruption of healthy tissue but rather by necrosis and ulceration due to extension of the infection. It is the caseous necrosis of the wall of a pulmonary vein for example which often establishes a channel by which bacilli gain access to the blood stream.

After sloughing and excavation have occurred the damaged tissue is left with a defect which varies according to the structure of the particular part involved. In the larynx the defect is apt to be a superficial ulcer in the middle ear a perforated drum and in the lung a parenchymal cavity. Some of the defects especially if the discharge from them does not drain freely

may be the seat of secondary infection with other bacteria.

*Healing and repair* of tuberculous lesions may occur at various points. If the infection subsides in the early inflammatory phase, the exudation of cells and fluids ceases and resolution of the accumulated products follows usually at a much slower rate than with other bacterial infections. If caseation has already set in as it does in most lesions of material size and duration resolution of the surrounding non necrotic exudate may occur but the necrotic centers still harboring bacilli remain to be dealt with. Such caseous residues if propitious conditions last undergo slow fibrous organization with some drying and shrinkage. Eventually the lesion may be converted into an irregular fibrocaseous mass or into a rounded structure enclosed wholly or in part by a fibrous envelope. This fibrosis may extend well beyond the center of the lesion. In time the caseous part of the fibrocaseous lesion may become infiltrated with mineral salts chiefly calcium phosphate from the body fluids. The process may proceed through a "chalky" phase to complete calcification or ossification. By this time the contained bacilli frequently

### TUBERCULOSIS DEATH RATES UNITED STATES Among Males and Females 1900\* and 1955

FIG 28 Additional curves (1945) are drawn in to indicate the accelerated decline of the death rates after specific chemotherapy became available. The general application of this started about 1947.

causes proportionately more deaths among American Indians and Chinese than it does among Negroes in the United States

Age and sex influence the behavior of the disease whether this originates in a recent primary infection or in a recent extension from remotely established lesions. Generalized tuberculosis is much more common in early childhood. Chronic pulmonary tuberculosis characteristically begins to appear in the second and third decades. The mortality experience with relation to sex and age is shown in Figure 28. It will be noted that in the United States the prevalence of fatal tuberculosis is greatest among elderly men, a phenomenon which is duplicated in many other countries.

**Physiological and Psychological Influences** Pregnancy aggravates tuberculosis in some women. Impaired nutrition may lower resistance. The increase in fatal tuberculosis in Europe during both World Wars seems to have been related largely to the drastic reduction of food which permitted a reactivation of previously latent pulmonary lesions. In World War II the disease was rife in German concentration camps such as Dachau and Buchenwald as well as certain prisoners of war camps where the nutritional deficiencies of some inmates reached the edema level. Anxiety and tension created by psychological maladjustments seem to lower resistance. There is some evidence that tuberculosis is more likely to develop in schizophrenics. The death rate is usually high in institutions for the mentally ill but this seems now to be ascribable chiefly to intimate exposure and inadequate care and to be largely correctable by isolating the infectious cases.

**Environment** Geographical location alone does not seem to be a major influence. Tuberculosis is a serious problem both in the Alaskan Indians and in Puerto Ricans. Social, economic and occupational factors are much more important. Ignorance, poor housing and overcrowding all are recognized as powerful evils. *Occupation* which is a good index of social economic status illustrates this strikingly. The death rate is highest among unskilled laborers and lowest among those in professions including physicians. A specifically dangerous occupation with relation to tuberculosis is that which involves exposure to silicious dust, e.g. metal moulding, sandblasting, mining, stone cutting and polishing, and manufacturing of abrasive soaps.

**Trauma** Previously healthy traumatized tissue is not liable to be invaded by tuberculosis except by direct extension from an im-

mediately adjacent lesion. Direct traumatization of tuberculous tissue however may be aggravating. Occasionally in pulmonary tuberculosis a severe trauma of the chest may result in such manifestations as hemoptysis, bronchial dissemination of the infection or pleural rupture with secondary empyema.

**Intercurrent Disease** Diabetes if uncontrolled especially in young people predisposes to serious tuberculosis. The phenomenon was conspicuous before the discovery of insulin. In hyperthyroid states native resistance may be relatively increased and Lurie finds experimental evidence that this may be due to greater activity of phagocytes and destruction of tubercle bacilli; the opposite may be found in hypothyroidism. Pulmonary tuberculosis is a frequent complication of congenital pulmonic stenosis but when present usually runs a relatively mild course in association with mitral stenosis. Tuberculous patients frequently withstand pneumococcal pneumonia well unless the functional reserve has been almost depleted previously. Necrotizing pneumonia or abscess however may lead to the breaking down of an arrested tuberculous focus and subsequent extension of the infection from it.

**Morbid Anatomy** The earliest reaction of the body to infection with tubercle bacilli is an accumulation of cells at the site. There is also some vascular congestion and exudation of fluid. While some pathologists believe that this early accumulation consists almost or entirely of a proliferation of local tissue cells which may go on directly to form the classic histological tubercle, Medlar submits experimental evidence that this is not the case but rather that the neutrophilic leukocyte predominates. According to him later developments depend on the rapidity of growth of tubercle bacilli. Leukocytes may continue to accumulate forming an abscess which may heal or if not may proceed slowly to liquefaction—much more slowly as a rule than the abscess produced by most other bacteria. When the reaction is not so intense the leukocytes may gradually be replaced by epithelioid cells (monocytes) and lymphocytes; these may be precursors or accompaniments of healing.

A frequent change in the early inflammatory lesion is *caseation*, a form of coagulative necrosis which as the name implies has the appearance and consistency of cheese. This rather dry necrotic matter may remain as such for many months after which it may liquefy or liquefaction

severe infections of the blood which however may be continued over a period of time perhaps with free intermissions. In this type of dissemination the natural clinical course instead of being rapidly fatal as in generalized miliary disease may be protracted while the lesions in their various sites such as the lungs lymph nodes serous membranes spleen kidneys and so on may enlarge caseate and show other local changes. Small and single or infrequent infections of the blood may set up one or a few isolated lesions which may heal or progress to local disease e.g. in bone eye kidney skin and so forth. Frequently there is a long period of latency before some of these local lesions exacerbate and become manifest clinically. Ustvedt and his co-workers found that this period ranged from five to more than fifteen years in the case of renal tuberculosis and was still longer with disease of the adrenal glands. Hemie dissemination due to the invasion of an artery occurs but rarely. Not infrequently hemie dissemination occurs as an early sequel of primary infection especially in young infants and as a terminal event in fatal chronic tuberculosis.

Another common route of dissemination is *intracanalicular* a term suggested to indicate channels such as the respiratory alimentary and urinary canals (exclusive of lymph and blood vessels). The most familiar example is related to the presence of a tuberculous cavity in the lung. The bacilliferous discharge from this source passes through the bronchi and is for the most part expectorated but sometimes is inhaled during breathing into healthy alveoli of one or both lungs setting up new secondary lesions. This is known as *bronchial dissemination*. The severity of the secondary lesions varies greatly depending somewhat on the rate of sloughing of the cavity the amount fluidity and bacillary content of the discharge and the general resistance of the patient. Large and abrupt disseminations such as may occur during a hemorrhage from the cavity may lead to acute confluent tuberculous lobular or lobar pneumonia but the more common pattern is a succession of smaller secondary lesions at intervals varying from days or weeks to many months. During periods of clinical arrest when there are no freely discharging cavities new secondary lesions seldom appear but the exacerbation and sloughing of old arrested lesions often marks a reactivation of these mechanisms and is the usual explanation of relapse. In

this way sooner or later chronic pulmonary tuberculosis often becomes established the lungs and pleura showing old fibrous scars along with new inflammatory and caseous lesions.

Contact infection of the mucous membrane by the discharge from a pulmonary cavity may cause lesions in the bronchi trachea or larynx the last being a fairly common site. Other loci include the middle ear infection here being carried more often via the eustachian tube than the blood stream the tongue and the lip (usually through abrasions). Infection seems to favor places where bacilli have fairly long contact. Thus when pus from the lungs is swallowed as often in chronic cases the alimentary organs usually escape until the lower ileum cecum and ascending colon are reached and the passage of contents slows. Tuberculous ulcers are found there in many advanced pulmonary cases. By similar mechanisms the rectal crypts may be infected and an ischio-rectal abscess may form.

Other manifestations of *intracanalicular* dissemination are from the kidney to the ureter and bladder and from prostate to epididymis.

From the foregoing it is easily seen that the lungs are peculiarly open to attack by tubercle bacilli which may find access through inhalational hemie and bronchial routes.

**Evolution of Primary Lesion.** The lung is the site of the primary lesion in more than 90 per cent of infected persons (Ghon). Other sites include the intestine (often ascribed to the ingestion of contaminated raw milk) tonsil skin and conjunctiva. The pulmonary lesion is usually single and situated in a lower lobe or lower part of an upper lobe. Progressive disease may ensue. Meningitis and generalized miliary tuberculosis are relatively common sequels in early childhood while in adolescence and adult life the clinical manifestations are more often traceable to the excavation of the pulmonary lesion and the spread of infection by way of the bronchi. Enlargement of the mediastinal lymph nodes is more often massive and extensive in children than in adults and there is a greater tendency for these extensively enlarged nodes to perforate the bronchi.

#### GENERAL CONSIDERATIONS IN CLINICAL DIAGNOSIS AND TREATMENT OF TUBERCULOSIS

**Tuberculin Tests.** A typical reaction to a standard tuberculin test is a specific indica-

die At any time if the bacilli survive the infection may be reactivated leading to an extension of the disease It is not uncommon to observe healing in one lesion while others progress Ulcers and cavities can be repaired only by fibrous organization and contraction The mucous membrane may grow back over a healed ulcer of the larynx for instance but destroyed alveoli of the lung are not restored Large cavities as of the lungs seldom heal completely by natural processes

An understanding of the time factor in healing is most important in clinical practice Marked resolution may be observed within several months but fibrous organization of the residual lesions is inevitably slow requiring many months or years In many cases largely because of the extent of caseous necrosis healing is incomplete and impermanent and the status at best can be regarded only as arrested

Chemotherapy may retard or halt active disease and accelerate healing but the essential processes of resolution and fibrous repair are not otherwise altered

**Pathogenesis** For many of the present concepts of pathogenesis we must look principally to the pathologist Interpretation of the findings is often difficult and the terminology used has sometimes been confusing In recent years there has been a tendency to discard such designations as *childhood type* and *adult type* of tuberculosis because they have no clear connotation Likewise *reactivation* or *exacerbation* of disease is suggested instead of *endogenous reinfection* to describe the renewed progression of lesions which previously had been inactive and perhaps partly healed

The inflammation which appears at the site of the primary infection is known as the *primary lesion* (in the lung sometimes called the Ghon focus) The combination of the primary lesion and that which usually appears simultaneously or soon thereafter in the tributary lymph nodes is the *primary complex* (Ranke) The complex may be incomplete in that the parenchymal or less often the lymph node focus may not be found but this is unusual A *reinfection lesion* is one caused by a new (exogenous) infection Pathological evidence of this is the finding for example of a recent lesion in the lung apparently unrelated to but existing with an old well healed and calcified primary complex The importance and frequency of reinfection (superinfection) in the presence of existing unhealed disease are not established So long as there is an unhealed focus in the body progres-

sive disease is much more likely to originate from this than from an exogenous reinfection After the primary complex has healed fully the possibility of reinfection seems to be vastly greater Thus Medlar found at autopsy that progressive "minimal pulmonary lesions in the bodies of 23 persons under forty years of age were a part of primary disease in 91 per cent while in 73 over forty years of age similar lesions were due to reinfection in 72 per cent

**Dissemination** Before further consideration of the various phases of tuberculosis the routes by which the infection is spread in the body should be recognized Any such lesion may extend locally *i.e.* by continuity and contiguity depending somewhat on the nature of the tissue barriers Thus it often spreads broadly over the pleural surface but it seldom penetrates the parietal pleura and invades the chest wall unless the membrane is broken (*e.g.* by needle puncture) *Lymphatic\** dissemination of the infection is observed most strikingly at the time of the primary infection as indicated by the tributary lymphadenitis it becomes lymphohemic if the bacilli are not retained in the nodes but are carried with the lymph—through the thoracic duct for instance—into the venous blood stream Uncommonly tuberculous lymphangitis may be set up along the route of spread Retrograde lymphatic extension *i.e.* against the lymph stream seldom if ever occurs

Two other common modes of dissemination depend on the tendency of lesions to slough and discharge after caseation One is *hemic* which is explained almost always by a caseous lesion invading and destroying the wall of a vein thus allowing bacilli to enter the blood stream The usual site is a pulmonary vein but others are also recognized such as a vein in a caseous prostate gland The results of hemic dissemination vary according to a number of factors the most important apparently being the mass and rate of discharge of bacilli from the caseous focus Acute generalized miliary tuberculosis is usually interpreted as the result of an abrupt infection of the blood with an overwhelming mass of bacilli Subacute and protracted generalized forms seem to be related to less

\* Certain terms dignified by usage are in their literal meaning quite incorrect as applied in pathogenesis For clearness in these paragraphs therefore the terms *lymphatic lymphohemic hemic and bronchial* are used instead of *lymphogenous lymphohematogenous hematogenous and bronchogenic* respectively

ease is still in its incubation period (five or six weeks after the primary infection sometimes longer) (2) if existing tuberculous lesions are thoroughly healed and calcified (3) in some terminal cases of tuberculosis (4) in the presence of severe acute exanthemata (5) in poorly understood anergic states such as that which occurs in cases of sarcoidosis and (6) if the dose of tuberculin is too small. Following the administration of cortisone or corticotropin the tuberculin sensitivity of the skin may be temporarily diminished.

**Demonstrating the Tubercle Bacilli \*** When possible the demonstration of the presence of tubercle bacilli is the final proof of the tuberculous nature of a lesion. Furthermore in clinical practice the recovery of the bacilli may be taken in most instances as evidence that the lesion in question is active or only partly healed. The reason for this is the fact that the organism does not escape readily from the lesion until caseation, liquefaction and ulceration have occurred. Unlike most other bacterial pneumonias for instance the early tuberculous pneumonia is composed of an exudate which is relatively dry and possibly coagulated and on this account does not "leak" into the bronchus; moreover at this time there is little or no tuberculous bronchitis. Bronchial discharges do not start until the parenchymal lesion sloughs; not until then are tubercle bacilli likely to be demonstrated in the sputum. According to the same principle the resulting defect or cavity cannot be said to have healed as long as bacilli are demonstrable. The same concept applies in other situations such as the finding of bacilli in the urine with respect to early tuberculosis of the kidney. Even after a lesion starts discharging its purulent contents it may do so slowly and in small quantities; bacilli may be recovered therefore only from isolated purulent particles or in a collection of the discharge such as sputum taken during several days. A few organisms from an early sloughing renal lesion may be greatly diluted in the urine and therefore hard to recover; consequently they must be concentrated again by centrifugation or some other method. Similarly in serous effu-

sions and in the pus of abscesses there may also be great dilution requiring artificial concentration before the bacilli can be demonstrated. In view of such circumstances therefore failure to detect the bacillus is not accepted as proof of its absence. However there are particular relationships in which this failure is highly significant, such as a "negative" purulent sputum which is being expectorated in considerable quantities from a pulmonary cavity. In such circumstances the lesion is unlikely to be tuberculous.

**Cultural methods and animal inoculation** are of great assistance if the specimens are carefully prepared. The former are more convenient and if skilful and meticulous techniques are used they are as efficient as animal inoculation. In either case the results may not be known for six or eight weeks. Consequently special methods have been developed to speed up bacterial growth. They include several media developed by Dubos and Middlebrook: a chick embryo medium suggested by Bunn and a slide culture method proposed by Pryce. The characteristics of virulence of tubercle bacilli have been studied by Middlebrook, Dubos and Pierce who observed the virulent forms growing on culture media in long serpentine cords. Dubos and Middlebrook have also described a cytochemical reaction with neutral red which appears characteristic of these forms. H. Bloch has identified a material of lipid character ("cord factor") which appears to coat the surface of the bacillus and to be closely related to its virulence. Organisms obtained from patients before they are treated with specific drugs are almost always found to be uniformly pathogenic for guinea pigs; variations in potential virulence are not known to be related to manifestations of human disease except in rare instances such as lupus vulgaris (Griffith). Attenuation of virulence is often observed however in bacilli obtained from patients who have been treated with isoniazid; these strains are usually found to be isoniazid resistant and catalase negative. Although their ability to produce tuberculosis in guinea pigs may be greatly reduced they may still retain their virulence in mice and hamsters. No other drug has been shown to have such effects.

One of the identifying marks of the tubercle bacillus is its *acid fast staining* by certain dyes. This characteristic is brought out by fixing the prepared specimen on a microscopic slide and applying the stain according to one of a number

\* Various bacteriological techniques adapted especially for the problems of tuberculosis are described in a booklet *Diagnostic Standard* which may be obtained from the National Tuberculosis Association, 1790 Broadway, New York City. A more comprehensive treatise is the book of Willis and Cummings *Diagnostic and Experimental Methods in Tuberculosis*, Springfield, Illinois: Charles C. Thomas, 1952.

tion of the presence of a tuberculous lesion somewhere in the body beyond this fact there is always the implication that the lesion probably contains living tubercle bacilli

**Indications for Testing** The tuberculin test is a valuable means of determining the prevalence of infection in a community. It often is a tracer of sources of infection e.g. a young child who reacts to tuberculin probably has been in contact at home or elsewhere with some person with tuberculosis in the infectious state. In such ways tuberculin testing is useful in communities where the disease is of low prevalence and is likely to exist in nests. In clinical practice it is often distinctly helpful in diagnosis.

**Materials and Techniques** Of the many tuberculins prepared from cultures of tubercle bacilli the two best known and most often employed are Purified Protein Derivative (PPD) developed by Seibert and Old Tuberculin (OT) first prepared by Robert Koch. The former is widely favored and is recommended by the National Tuberculosis Association. A special batch known as PPD S has been adopted by the World Health Organization as the international standard tuberculin. The international tuberculin unit (TU) is specified to be that amount of PPD which is equal in potency to 0.00002 mg of PPD S.

For general use with the intracutaneous (Mantoux) test a solution is prepared so that 0.1 ml contains 5 TU of PPD or an equivalent amount of OT (This is approximately 0.05 mg of OT of standard potency and is administered as 0.1 ml of a 1:2000 dilution of OT.) This precise dose is recommended especially by C. E. Palmer and his associates because larger doses are thought sometimes to elicit reactions which are not specific for tuberculosis.

The test is usually performed on the volar surface of the forearm. Using a calibrated syringe and a 25 or 26 gauge needle 0.1 ml of the solution containing the specified dose (5 TU) is injected into the skin close to the surface producing a wheal. The site is inspected and palpated within forty-eight to seventy-two hours after the injection. Empirically an area of induration greater than 5 mm in diameter is considered to represent a positive reaction. Lesser induration is doubtful and may be nonspecific. The central area of induration is usually surrounded by a zone of erythema but erythema without induration is not interpreted as a specific reaction.

Tuberculins which are presently avail-

able are known to vary considerably in their potency and may not conform to the standard. Partly on this account and partly because of time honored practice many physicians confronted with clinical diagnostic problems test initially with 0.1 mg of OT (0.1 ml of a 1:1000 dilution of OT) or sometimes with a lower dose (0.01 mg of OT) if no reaction occurs a second test is often done with ten times the initial dose of OT. Similarly in the presence of disease of doubtful etiology some test initially with 0.00002 mg of commercially available PPD going on to a higher dose for a second test if the first is negative. Severe reactions may result in the formation of a vesicle with necrosis of the tissues and there may be pink streaks of lymphangitis extending up the forearm and palpable slightly tender nodes in the axilla. A *percutaneous* or *patch test* is performed by applying to the skin a strip of adhesive tape on which a piece of gauze saturated with dried tuberculin is attached. The local reaction is represented after forty-eight to ninety-six hours by a red papular and occasionally slightly vesicular eruption. The patch test is said to approximate in accuracy the Mantoux test using 0.1 mg of OT; most observers however do not rely on it as a fine index of tuberculin allergy. Its chief virtue is the simplicity of its application; it may be placed on the back which is desirable for children. If no reaction occurs the more dependable Mantoux test may be used. A multiple puncture test (Heaf) is performed with a special instrument and is reputed to be quick and painless. The older scarification (Pirquet) test is not often used today.

In addition to the local reaction to any tuberculin test there may be a constitutional reaction with fever and malaise and less often a focal reaction of inflammation about tuberculous lesions. These should be guarded against by carefully selecting the dose of tuberculin.

**Interpretation of Cutaneous Hypersensitivity to Tuberculin** An infant who reacts to tuberculin is assumed to have an active tuberculous lesion due to a recent primary infection. In older persons the lesion may be old and fibrotic and therefore inactive. In the presence of manifest disease of uncertain causation a reaction is of little or no practical diagnostic value but no reaction is significant since the disease in these circumstances is unlikely to be tuberculous. The test is not a measure of immunity or of the degree of activity of the disease in the individual case. The reaction may be depressed or absent (1) if the dis-

are interpreted to correlate closely with clinical manifestations. However in all of these tests the exceptions are too numerous to justify the routine use of the tests either for differential diagnosis or for the determination of the activity of a tuberculous process. A number of observers among whom may be mentioned Florence Seibert, Zitrin and Maher and their respective associates have been interested in the determination by electrophoretic or chemical methods of the protein fractions of the serum and some suggest rather guardedly that variations noted especially in serial tests may be of prognostic value. During active phases of the disease there is a rise in the gamma globulin fraction and the albumin decreases; the latter returns to normal as the activity of the disease subsides while the gamma fraction according to Maher remains slightly elevated. With these initial disturbances there may also be an elevation of the alpha fractions and less significantly of the beta fractions. Hirsch and Cattaneo found an increase in protein bound carbohydrate which they consider to bear a close relationship to the clinical activity of tuberculous processes. They think chemical determinations may suffice for clinical purposes and Zitrin has the same view with respect to globulin. C reactive protein also appears in the serum of patients with active tuberculosis. Walsh and his associates found its presence to be correlated in active disease with the erythrocyte sedimentation rate but the absence of C reactive protein was a better index of inactivity of the disease than the latter. In the late stages of tuberculosis there may be other changes including a lowering of the blood volume and of the content of mineral salts, enzymes and vitamins. Bacteremia must occur obviously during hemic disseminations and occasionally may be demonstrated culturally. Most efforts however are unsuccessful probably because of the degree of dilution of the bacilli and their rapid disappearance into phagocytes which become immobilized.

There is no reliable specific test of resistance or immunity against tuberculosis nor is there a good prognostic test in chronic forms of the disease. These factors are best judged by a summation and evaluation of routine clinical roentgenographic and laboratory data.

**Toxicity of Tuberculosis.** No true toxin has been identified as a product of the tubercle bacillus. Various chemical components of it and by products of its growth in artificial culture media can be intro-

duced into the tissues of a healthy animal without appreciable harm. If the tissues are allergic because of previous infection however there may be definite and severe reactions as with the tuberculin test. The mechanisms of this phenomenon are complex and unclear. The toxicity is characterized by its relative mildness. In the early phases of tuberculosis often enough there are no subjective general symptoms. Usually it is only after the disease has advanced and caused considerable involvement of tissues that loss of weight, anorexia and fever occur. This disproportion between volume of disease and mildness of symptoms is almost unique and often gives a clue to the diagnosis.

In some cases the chronic toxicity of the disease predisposes to the development of amyloidosis. However the majority of fatal pulmonary cases are not associated with this complication. It is observed most often in association with secondarily infected lesions of the bones and joints in mixed infection, tuberculous empyema and in cases of severe intestinal tuberculosis complicating pulmonary disease.

The symptomatology local as well as general is considered in more detail in the sections dealing with various forms of the disease. Emphasis is placed on the pulmonary form because this is the most frequent in clinical practice.

Likewise the principles of treatment will be described with special reference to tuberculosis of the lungs and to problems related to other specific sites of the disease. Since the antituberculosis drugs have certain similar effects on all forms of tuberculosis a general description of their actions will be given at this point.

#### SPECIFIC CHEMOTHERAPY FOR TUBERCULOSIS

The *in vitro* growth of the tubercle bacillus is inhibited by an enormous range of organic compounds few of which exhibit *in vivo* activity. To merit classification as a tuberculostat of interest therefore a compound should possess marked activity *in vivo* (H. H. Fox). To be of practical value it may be said in addition the compound should not have serious toxic effects when administered in effective therapeutic doses.

The searches of investigators during the centuries culminated in the discovery of effective compounds as well as recognition of the therapeutic properties in others which were known but not previously tested. In 1944 streptomycin derived from *Streptomyces griseus* was announced as a discovery by Schatz, Bugie and Waksman. Feldman and Hinshaw soon observed its tuberculostatic influence in experimental animals and treated patients. In 1946 Lehmann reported the favorable effects of para-aminosalicylic acid (PAS). The announcements of other discoveries followed; these included amthio-

of techniques usually the Ziehl-Neelsen. With this a carbol fuchsin stain is applied followed by acid alcohol to bleach all organisms except the mycobacteria which retain the red color. With rare exceptions such acid fast organisms in expectorated sputum are tubercle bacilli. However gastric specimens taken when the sputum is negative should be cultured since these often contain nonpathogenic saprophytic mycobacteria ingested with food such as raw vegetables and fruits. Similarly acid fast saprophytes indigenous to the cerumen of the external auditory canal and the external genitalia (smegma bacillus) must be differentiated when specimens of pus or urine are taken for diagnosis. These nonpathogenic and atypical mycobacteria may be distinguished by their cultural characteristics and in other ways (See Other Mycobacterial Diseases p. 293).

**Secondary infection of tuberculous lesions** including effusions and abscesses rarely occurs by way of the blood or lymph streams. Its presence usually is explained by communication with the respiratory or alimentary canals or with the external surface of the body after a sinus, fistula or cavity has formed; then the common pyogenic bacteria may gain access. Occasionally they are introduced by faulty technique as in thoracentesis. The effect may be serious if drainage is poor or if there is a dead space causing a mechanical hindrance to healing (e.g. pleural empyema) or it may be inconsequential. Thus a tuberculous pulmonary cavity is not usually aggravated by secondary infection unless a blockage of the bronchi interferes with free drainage of the discharges.

**Surgical Biopsy and Diagnostic Aspiration** In difficult cases especially when it is urgent to make the diagnosis promptly so that appropriate treatment may be started, biopsies of tissues which are obviously or probably involved in the disease may be obtained through a surgical incision or by the use of a special needle. When granulomatous lesions are found in the specimen special bacterial staining is often necessary to help make the distinction between tuberculosis, fungus infection, sarcoidosis and beryllium granulomatosis; the demonstration of true caseation however is usually accepted as presumptive evidence of tuberculosis. The aspiration with syringe and needle of serous tuberculous effusions is usually harmless if good judgment and technique are used. If the effusion is purulent and teeming with tubercle bacilli special precautions

should be used to avoid infection of the needle track which sometimes leads to necrosis and the formation of sinuses and fistulas. Precaution should also be exercised to avoid the perforation or laceration of underlying structures for this reason it may be preferable to obtain the specimen of fluid by making a small surgical incision. This for instance should avoid puncturing the intestine if it should be bound to the parietal peritoneum by tuberculous or other plastic exudate. The danger of reactivating or aggravating a local lesion by any of these procedures or of spreading the infection may be minimized by chemotherapy.

**Changes in the Blood of Tuberculous Patients** In the early phases of tuberculosis significant changes in the cells of the blood are seldom detected. During insidious progression of the disease there may be no rise in the total number of leukocytes though there may be some increase of the young forms and of monocytes while lymphocytes may be relatively decreased. During acute exacerbations these tendencies may be greatly accentuated; the polymorphonuclear leukocytes may rise to 12,000 to 18,000 per cu mm (seldom above 20,000) while the percentage of neutrophils also increases but not often above 80 per cent. Higher ranges always raise the question of some other bacterial infection and in this way are often helpful in differential diagnosis. If and when the disease settles back to a quiescent chronic or healed state the numbers and proportions of leukocytes usually return almost or entirely to normal. The erythrocytes and their hemoglobin content usually remain normal until there has been considerable progression of the disease when slight anemia may appear. Severe grades are observed in the late stages of the disease especially if it is complicated with intestinal involvement or amyloidosis.

The sedimentation rate of the erythrocytes is accelerated in almost all the febrile phases of tuberculosis. Also it may be accelerated in many of the afebrile phases and thus may be a more sensitive index of activity than the temperature curve. Its value is limited by the fact that it is not specific for tuberculosis and may be normal in the early active phases and also later when the lesions have become chronic although not healed. The same limitation applies to other activity tests of which there have been many. Specific complement fixation and hemagglutinin tests for tuberculosis frequently yield findings which

months or longer may contain numerous tubercle bacilli which take the acid fast stain but fail to grow in artificial media or to produce disease in the usually susceptible animals. There is evidence to indicate that some of these organisms are dead and that the habits of growth and reproduction of others are profoundly modified. The same phenomena have been identified in lesions from patients who have never had specific chemotherapy but the time required for such modifications under natural conditions appears to be much longer. In contrast tubercle bacilli obtained from "open cavities of the lung" (i.e. with free bronchial communications) are found more often to be demonstrably viable and virulent, an exception with respect to isoniazid will be mentioned.

As mentioned before the effects of specific chemotherapy on tuberculous lesions and clinical symptoms do not differ essentially from the effects of natural regression of the disease without such aid. However with the relatively rapid bacteriostasis induced by chemotherapy the favorable response is usually more surely predictable, more prompt and more consistently sustained. So far as known chemotherapy merely holds the infection effectively in abeyance and thus allows nature to take its course unhindered by the continuing attack of actively growing tubercle bacilli. When the natural defenses are poor or entirely lacking even the most potent drugs are unavailing. The well known but immeasurable variability of these defenses helps to account for differences in the behavior of individual cases and to support the concept that each patient is a law unto himself.

In most cases the early response to treatment is a cessation of exudation in and about lesions and a diminution of constitutional symptoms. As fever subsides for instance edematous swellings recede and the pain from this tissue tension eases and vanishes. Accumulated exudate then is removed by resolution, absorption and drainage. Here again the rate is variable. Fibrous repair ensues and proceeds its adequacy in the long run depending on the damage done beforehand by the necrosing effects of the infection. Eventually as with any antituberculosis treatment the outcome is determined not only by this healing but also by the persistence of partly repaired necrotic ulcerous excavated tissue which harbors tubercle bacilli ready to renew the attack.

#### Action of Individual Drugs *Streptomycin*

in a dilution of 1:56 micrograms per milliliter of artificial culture medium completely inhibits the growth of almost all human and bovine strains of tubercle bacilli; the avian strain is said to be more resistant. The action of the drug is somewhat inhibited in an acidic medium or in one containing nucleic acids conditions which exist in some tuberculous abscesses and cavities. Resistant strains assumed to exist in rare numbers in any "wild" bacterial colony proliferate *in vitro* and *in vivo* so that after about four weeks of exposure to the drug they begin to predominate. At the end of 120 days 80 to 90 per cent of the cultures are found to be resistant to more than 10 micrograms of streptomycin per milliliter; many will resist the effects of 1000 micrograms or more. However the virulence of resistant organisms is not appreciably altered. In clinical practice the emergence of resistance is found to depend more on the duration of treatment than on daily dosage; however the rate of assuming predominance is slower if the drug is given only twice a week in 10 gm doses. Streptomycin is generally administered by intramuscular injection; if indicated it may also be given intrathecally. Oral administration is ineffective for tuberculosis because of the poor absorbability of the drug and inhalation of the aerosol is avoided because of the lack of demonstrated advantage and its tendency to cause a sensitization of the tissues.

Toxic effects principally on the vestibular apparatus are frequent when streptomycin is administered intramuscularly in doses amounting to 2.0 gm daily for two to four months or longer; their incidence is much less when the dose is reduced to 1.0 gm daily and still less on a regimen of 1.0 gm twice weekly. Vestibular dysfunction appears as vertigo, nausea, vomiting, ataxia and partial or complete loss of response to caloric stimulation; if severe this loss may be permanent but there may be partial recovery from mild damage. Less frequently impairment of the auditory function may occur, usually preceded by tinnitus. Deafness is of the perceptive type according to Winston. Other disturbances include dermatitis which occasionally may be severe and exfoliative, eosinophilia and renal damage. Neurotoxic effects on the fetus have not been reported and it is considered safe to give the drug during pregnancy. A few nurses and others who have direct contact with streptomycin in handling it are observed to develop hyper-

zone (4 acetylaminobenzaldehyde-thiosemicarbazone) and a number of other related compounds and viomycin (derived from *Streptomyces puniceus* and *Streptomyces floridae*). Meanwhile drugs which are distinguished for their action against other bacteria were also found to have some tuberculostatic effect: these include especially diammodiphenyl sulfone and its derivatives (Promin, Diasone, Sulphethone and Promizole) and oxytetracycline (Terramycin). In 1952 Robitzek and Selkoff reported strikingly favorable effects of isoniazid (isonicotinic acid hydrazide) and iproniazid (1 isonicotinyl 2 isopropyl hydrazine) in tuberculous humans. Their work was preceded by the experimental investigations of Grunberg and Schnitzer, Zieper and Lewis, Bernstein, Steinken and Wohinsky, Benson, Rubin and the associates of all these. Also in early 1952 the antituberculous activity of pyrazinamide, a derivative of nicotinic acid, was demonstrated in humans by Yeager and his associates after laboratory studies by Kushner and Malone and their respective associates. The antituberculous activity of cycloserine, an antibiotic discovered by Harned and Kropp and isolated from *Streptomyces orchidaceus*, was reported by Epstein and others in 1954. The discovery of another streptovaricin obtained from *Streptomyces spectabilis* was announced in 1956 by Summoff, Smith, Sokoloski and Savage. Both of these have considerable activity also against a number of other bacteria. (Another antibiotic, kanamycin, has been isolated by Umezawa and his associates from *Streptomyces kanamyceticus*. Preliminary reports indicate that this has some properties similar in those of neomycin but it is less toxic. It appears to have significant activity against tuberculosis in animals and is receiving clinical trials.)

As each of these agents became available they received clinical testing in various parts of the world. The reports clearly indicated some merit in each compound. It was soon appreciated, however, because of the known wide variations in the natural course of tuberculosis and the complexity of the problems implicit in the new treatments that organized studies of many hundreds of patients would have to be undertaken. Such organization in many cooperating hospitals was arranged by the United States Public Health Service, the United States Veterans Administration, Army and Navy Hospitals, and the British Medical Research Council, and thus together with thousands of individual efforts has accomplished great progress.

The relatively high potencies of streptomycin and isoniazid have been satisfactorily demonstrated. PAS, while less effective, has retained an important place for reasons to be mentioned. The other drugs enumerated above have relatively limited effects and several have all but fallen into disuse, especially since the advent of isoniazid. At the start each drug, in its turn, was tried singly; this had the virtue of demonstrating any toxic properties and the degree and range of therapeutic effects. It soon became evident that almost all the compounds and certainly the more potent of them when given to patients suppress the growth of offending tubercle bacilli, except those which are drug resistant; these resistant strains then may take over

the field and escape the effects of any further therapy with the given drug. Such drug resistance becomes manifest at varying rates but commonly within two to four months after the start of treatment. As a consequence the early favorable response frequently is followed by a relapse. Then it was found that the growth of resistant strains may be suppressed to a greater or lesser extent by exposing them to drugs of another class and this was the genesis of combined therapy, i.e., administering two or more drugs simultaneously. Regimens employing two drugs are effective in preventing the proliferation of resistant strains for long periods of time, at least four months, and in most cases apparently for a year or more. Although under certain conditions such as extremely acute disease the use of three-drug regimens may have some additional influence in delaying manifestations of drug resistance, this superiority appears to be slight and not demonstrable in most clinical situations. Usually it is considered wiser to hold one very potent drug in reserve for use in meeting possible needs such as a later relapse. Drugs are not usually prescribed singly for the treatment of active disease, but isoniazid is sometimes given alone (e.g., during the administration of adrenal corticosteroids) as a prophylactic against the reactivation of latent tuberculous lesions.

**Common Effects of Chemotherapy.** The mechanisms of antimycobacterial action of the drugs appear to be complex according to various studies. Whatever these may be, the outward manifestation is the failure of susceptible organisms to reproduce at least at the usual rate so long as they are exposed to effective quantities of the given drug. This interference with the reproductive cycle may continue in the tissues for many months, then after discontinuance of treatment bacterial activity may sooner or later resume its familiar course. Lesions removed surgically may yield organisms which grow in animals or in artificial media. In such instances the effect is obviously more or less prolonged bacteriostasis. There is other evidence from the laboratory that in certain circumstances some of the bacteria actually may be killed by specific drugs and this is thought by Middlebrook and others to apply especially to young forms. It has been found by many that more or less encapsulated lesions of solid caseous composition, removed surgically from the lungs of patients who have been treated with drugs for four

a daily oral dosage of 5 mg of isoniazid per kg of body weight divided into three doses of about 50 to 100 mg each will maintain an adequate therapeutic concentration in the blood and other tissues in urgent cases such as those of meningitis the dose is usually doubled partly because the cerebrospinal fluid concentration is found to be only two thirds that of the serum. In practice the response of tuberculosis to such doses of isoniazid (given with some other antituberculous drug) is usually satisfactory. However there are exceptions and some of these have been ascribed to the rapid metabolism and elimination of isoniazid. Hughes, Schmidt and Biehl (1955) reported marked variations in this process especially in treated tuberculous patients. The output of free isoniazid and its hydrazones (both biologically active against the tubercle bacillus) in the urine was found to be in inverse proportion to that of acetyl isoniazid and isonicotinic acid (biologically inactive). The pattern of metabolism was shown to be constant in individuals but to vary widely from one patient to another. Interest has centered on the process of acetylation which results in inactivation of the drug. Kass and his associates (1957) report that approximately one third of their patients were found to be rapid inactivators and suggest compensating for this by administering 8 to 16 mg of isoniazid per kg daily together with 10 gm of PAS or PABA. This they claim will be adequate for 95 per cent of white Americans. The use in this way of PAS or PABA is based on the observation by Morse *et al.* (1956), Bell and Mitchell (1957) and others that these and other aromatic amines compete in the process of acetylation and thus spare isoniazid in its free and active form. A method for the quantitative determination of isoniazid and PAS in fluids of the body introduced by Maher and his associates (1957) may serve in this respect as a guide of proper dosages.

Since the hydrazones of isoniazid are also active against the tubercle bacilli several of these and other compounds have been investigated for possible clinical usefulness especially since some are thought to have a low order of toxicity. These include INHG (Galatone, Mycobactyl 1) a glucuronolactone derivative, INSH (Salizid) a hydrazone with salicylaldehyde, Verazide (3,4-dimethoxybenzal isonicotinyl hydrazone) and Phthivazid. With some of these the therapeutic effect is thought to depend somewhat on the liberation of free

isoniazid in the body. In cyanacetic acid hydrazone an aliphatic ring is substituted for a pyridine ring of isoniazid and this modification is also tuberculostatic. However it has not been found to possess advantages in clinical use and it does not have any effect against isoniazid resistant tubercle bacilli.

*Para-aminosalicylic acid* in concentrations of approximately 15 to 20 micrograms per milliliter inhibits the growth of tubercle bacilli in artificial culture media. This inhibitory power may be greater or less in media of varying composition and it is assumed that the effects *in vivo* also vary according to the nature of the diseased tissue. The efficiency of PAS in clinical treatment is significant but less than that of isoniazid or streptomycin. Among patients treated with PAS alone for four months and continuing at that time to discharge tubercle bacilli the organisms have been found to be resistant to 10 micrograms or more of the drug per milliliter of artificial culture medium in 50 per cent or more of the cases. PAS is rapidly metabolized in the body largely by acetylation and excreted but following the usual dosage a concentration of 20 to 50 mg per 100 ml is maintained in the blood. In practice 12 to 15 gm of the drug are prescribed to be taken daily by mouth. This is divided into three equal doses and taken after meals. A common problem is that caused by gastrointestinal irritation manifested by diarrhea, nausea and vomiting in varying degrees. To overcome or mitigate this numerous devices have been tried including the use of solutions (which deteriorate rapidly and liberate toxic substances), capsules, tablets and coated granules. A resin complex with PAS (Rezipas) is more tolerable by some patients; also the sodium, potassium or calcium salts. These and a number of other PAS compounds are reputed to have advantages but the sodium salt is preferred generally if it is well tolerated. None of them can be held blameless in the production of hypersensitivity with febrile and other reactions which are not uncommon and may be dangerous. In some patients desensitization starting with minute doses of the drug and gradually increasing has been successful but others may never become tolerant. In some instances PAS causes hypoprothrombinemia of slight degree (Lanner 1953) also it has been found to interfere in some with the conversion by the thyroid gland of iodine to the organic iodide (Sutherland 1953). During pregnancy or in the presence of congestive heart

sensitivity to the drug: simple preventive measures such as wearing rubber gloves seem to be effective.

*Dihydrostreptomycin* has bacteriostatic effects similar to those of streptomycin and has been used in the same dosage. While dihydrostreptomycin causes less frequent disturbance of vestibular function deafness is a more common result of its use; the onset may be rather abrupt and it may not appear until a few weeks after the treatment has been discontinued. Other toxic effects are much like those of streptomycin though dihydrostreptomycin may be well tolerated by patients who are hypersensitive to streptomycin.

Several devices have been tried to avoid the neurotoxic effects of these drugs. These include substituting a combination of half the usual dose of the two forms (e.g. 0.5 gm of streptomycin plus 0.5 gm of dihydrostreptomycin) for the full dose of either alone or administering streptomycin in the form of the pantothenate. Except in the acute forms of tuberculosis however the usual practice is to restrict the dose of streptomycin to 1.0 gm and to administer this only at intervals of two or three days. Dihydrostreptomycin may be substituted for streptomycin when indicated but the former has no effect against bacilli which are resistant to the latter and vice versa.

*Isoniazid* is a superior therapeutic agent against tuberculosis. As *iproniazid* produced troublesome toxic effects when given in therapeutic doses it is not in general use at present. Isoniazid inhibits the growth of virulent tubercle bacilli in culture media in concentrations of 0.05 to 0.25 microgram per milliliter. Elmendorf and his associates found plasma concentrations of the drug five to ten times these concentrations at the end of three hours in patients given doses totalling 3 mg per kilogram per day. The drug may be given orally and also parenterally. Isoniazid passes through tissue barriers readily and when taken by mouth it is found in considerable concentration in the cerebrospinal fluid. The drug penetrates caseous tuberculous lesions (R. W. Mather *et al.*) apparently more readily than streptomycin. It also inhibits the growth of tubercle bacilli within isolated rabbit macrophages in a concentration of 0.05 microgram per milliliter compared with 25 micrograms of streptomycin required for a similar effect (Mackanes and Smith).

When isoniazid is administered alone for periods of six to seven months and

tubercle bacilli are still present in the sputum these are found to be resistant to 5 micrograms of the drug per milliliter of medium in 50 per cent or more of the cases (U. S. Public Health Service Study). As mentioned above (Cultural Methods and Animal Inoculation ■ 253) a unique feature of some of these strains is their loss of pathogenicity for some species of animals but not for others. The significance of these phenomena is not clear. To what extent if any such attenuation of virulence applies in tuberculous persons is not known. Some have been observed to continue with progressive disease while discharging bacilli of low pathogenicity for guinea pigs but as a rule such patients do well. There are also isolated instances of persons developing disease anew after infection with bacilli of such character.

A great advantage of isoniazid is its relatively low toxicity. The development of hypersensitivity to this drug is very infrequent and when it does occur it is sometimes in patients who have become hypersensitive to PAS and/or streptomycin previously or simultaneously. The condition manifested by fever, eosinophilia, neutropenia, hemolytic anemia, purpura and lymphadenopathy has infrequently been serious and even fatal. Usually however it subsides when the administration of the drug is discontinued and appropriate treatment is given. Isoniazid taken by mouth does not irritate the gastrointestinal mucosa. (In large doses [25 mg per kg] it may cause hepatic damage in animals.) In adult humans doses of 20 to 30 mg per kg daily prove to be toxic in almost half of the patients and this has been found to be largely a consequence of the development of pyridoxine deficiency in children; such deficiency is not observed (Lincoln and Morales 1957). Toxicity is manifested most often by peripheral neuritis, muscular twitching, hyperreflexia, difficulty in micturition and constipation, rarely optic neuritis, clonic convulsions or temporary psychoses. The occurrence of toxic symptoms is infrequent during the administration of 5 to 10 mg of isoniazid per kg daily; then they are mild and usually disappear as the dose is reduced. With very large doses peripheral neuritis is usually prevented by the simultaneous administration of pyridoxine orally. Carlson and his associates suggest for adults 25 mg of pyridoxine for 8 mg of isoniazid per kg per day and 50 mg of pyridoxine for 16 mg of isoniazid per kg per day.

Until recently it had been assumed that

be given in four equally divided doses separately. This seems to avoid peak blood concentrations which are liable to be toxic. Some interest is now (1957-1958) centering on the clinical study of the therapeutic merits of a daily regimen of 4.0 to 5.0 mg of isoniazid per kg of body weight plus 0.5 gm of cycloserine divided into two equal individual doses. While the early reports indicate that objectionable side effects are less than those of a regimen of isoniazid and PAS the therapeutic efficacy of the latter is superior. It is generally agreed that cycloserine should be administered only in a hospital where close observation of the patient's course can be maintained.

Oxytetracycline, tetracycline and chlor tetracycline are relatively weakly tuberculostatic *in vivo* and approximately equally so according to Hobby although she found the first of these to be more active than the others *in vitro*. Oxytetracycline has had the more extensive clinical trials. Administered in company with a more potent drug the eventual predominance of strains of tubercle bacilli resistant to the latter is delayed but this may not be for a long time. A combination of viomycin 2.0 gm intramuscularly twice weekly and oxytetracycline (Terramycin) 2.0 to 4.0 gm orally is suggested by McMurdoch and Stewart as a second defense regimen *ie* after the effects of a better combination have been exhausted.

Streptolaricin and Kanamycin are newcomers undergoing trial. The former appears to be less effective in clinical treatment than streptomycin or isoniazid. Claims have been made that the latter is a potent antituberculous drug without serious toxicity. Preliminary accounts of clinical experience with the drug mention the occurrence of cylindruria and neurotoxicity but the gravity of these is not yet known.

Amithiozone and the sulfones have relatively weak bacteriostatic effects in doses which can be tolerated by most patients. Amithiozone may cause disturbances of hepatic function and blood formation although these usually correct themselves when the use of the drug is discontinued. *Hinconstarch* described by Barry (1954-1956) as a polymer from periodate oxidized potato starch with an equimolar mixture of isoniazid and p-aminobenzalthiosemicarbazone (PABT) has been found effective in the treatment of tuberculosis. However Katz and his co-workers (1957) observed toxic effects suspected to be chargeable against the thiosemicarbazone fraction

which with the isoniazid may be liberated in the body.

Neomycin is tuberculostatic but has highly toxic effects on the kidney and auditory function. On this account it is not considered safe to be included in any of the usual regimens. However it is sometimes applied topically in infected tissues because of its activity against bacteria other than tubercle bacilli *eg* in the infected pleural cavity after a surgical operation in this area.

Among many other substances which have been studied because of their tuberculostatic activity may be mentioned substituted thioureas, diphenyl compounds, thioethyl compounds and sulphydryl compounds.

**Combined Regimens** In the present-day treatment of tuberculosis with drugs two important principles are to be recognized. The first is that such therapy restrains the multiplication of drug susceptible tubercle bacilli and leads to the death of some but has no effect whatsoever on bacilli which are resistant to the drugs being employed. It cannot be assumed that lesions are sterilized particularly the caseous necrotic lesions which are present in all cases of clinical disease. The second principle is in a sense a corollary of the first namely since it should be assumed that tubercle bacilli continue living in the body throughout any course of treatment and for an indefinite time afterwards and since a lengthy period of time is required for lesions to become so firmly healed that the remaining bacilli will be permanently contained the treatment should be planned to exert its bacteriostatic effect continuously for a long time—many months or even years. This is achieved at least in part by administering two drugs concomitantly (sometimes three in urgent cases) in a regimen which is known usually to be effective and relatively safe and continuing this without interruption according to the degree of response for an arbitrary period of time beyond the point at which clinical symptoms of active infection have disappeared and anatomical repair of the lesions seems to be well on its way. The time required to arrive at this point varies greatly according to circumstances particularly the extent of destructive disease and usually will be shortened by rest treatment in the early and active stages.

Comprehensive and statistically controlled studies in United States Veterans Administration and other hospitals have provided many sound guides for the choice

failure the potassium salt may be substituted for the sodium

*Viomycin* is reported by Steenken and Wolinsky to have about 25 per cent of the potency of streptomycin in tuberculous animals. This drug is active against strains of tubercle bacilli which are resistant to other drugs and may be used in situations where the effects of other chemotherapy have been exhausted. In daily doses of 50 mg per kg it may have toxic effects including renal damage, hypokalemia and deafness. Regimens which have been found to be helpful and usually well tolerated when needed are: (a) *viomycin* 1.0 gm by intramuscular injection in the morning and again in the afternoon repeated every third day together with 12 gm of PAS daily; (b) *viomycin* in the same dosage and pyrazinamide (see below) 20 to 30 mg per kg of body weight daily divided into three equal doses and taken by mouth after meals. These regimens which are not very potent are not usually employed for periods of more than three or four months but they may be continued if there are no signs of toxicity. The latter is sometimes prescribed during some critical situation such as the surgical resection of diseased pulmonary tissue from a patient whose tubercle bacilli are known or assumed to have become resistant to isoniazid, streptomycin and para-aminosalicylic acid during the previous course of treatment.

*Pyrazinamide* inhibits the growth of tubercle bacilli of human origin but not bovine strains. Resistant strains are also found among wild colonies of the human type (Wasz Hockert and others 1956). *Pyrazinamide* was reported by its discoverers to have a tuberculostatic effect greater than that of PAS but less than that of streptomycin. During treatment with *pyrazinamide* alone resistant strains of tubercle bacilli assume predominance relatively rapidly as compared with this phenomenon with respect to streptomycin or isoniazid. A peculiar effect of *pyrazinamide* *in vitro* is the more rapid development of drug resistance when the medium is made acidic (Steenken and others 1957). Experimentally in diseased animals treatment with *pyrazinamide* together with isoniazid has been found highly efficacious but it has not been feasible to reproduce this advantage in human patients because of the toxicity of *pyrazinamide* in highly effective therapeutic doses (Muschenheim and others 1955). The restriction of daily dosage to the range of 20 to 30 mg per kg of body weight does not completely avoid the toxicity

which is manifested commonly as hepatitis. This may become evident clinically before the standard liver function tests deviate from the normal. Usually the damaged liver heals itself when the drug is stopped but several fatal cases have been reported. The effects of treatment therefore should be observed closely. During the administration of *pyrazinamide* in daily doses of 3.0 gm the concentration of uric acid in the blood serum has been observed to rise to 9 mg per 100 ml and some of the patients develop symptoms of gout. The effect appears to take place in the renal tubules (Cullen and others 1957). The abnormality rights itself when the drug is withdrawn from the regimen.

*Cycloserine* is reported by Steenken and Wolinsky to inhibit the growth of human virulent strains of tubercle bacilli in concentrations of 6.25 micrograms per milliliter of liquid medium and 20 micrograms per cubic centimeter of solid medium. Horse serum in the medium decreases the susceptibility of the organisms. They also found bovine and avian strains to be relatively less susceptible to the effects of the drug. Except in monkeys *cycloserine* has no significant effect against tuberculosis in experimental animals (guinea pig, mouse, rabbit). A peculiarity which may be related to the very rapid elimination of the drug after its administration (Conzelman and Jones 1956). *Cycloserine* is active against tubercle bacilli which are resistant to the effects of streptomycin, PAS or isoniazid. During treatment with *cycloserine* alone strains of bacilli which are resistant to the effects of this drug appear in a relatively short time.

In clinical practice *cycloserine* has been reported to be somewhat less effective against tuberculosis than streptomycin or isoniazid. A limiting factor is the neurotoxicity of *cycloserine* which may be manifested in depressant or excitatory effects including somnolence, convulsions, mental and motor disorders (the latter may be epileptiform), dizziness and occasionally fever and chills. Daily doses exceeding 25 mg per kg of body weight have been found to produce toxic reactions in almost all cases (Barclay and others 1957). Storey and McLean have summarized the experience and conclude that the convulsive effects are related to the total daily dose and to the size of the individual dose administered. These effects are diminished or abolished if the total daily dose does not exceed 0.5 gm taken orally and the individual dose does not exceed 0.25 gm. Likewise a total daily dose of 1.0 gm should

early adulthood and its subsequent prevalence seem to be related largely to constitutional or endocrine influences causing, in some people a lowering of resistance to the stress and strain of environment and to the more frequent acquisition of infection as people circulate more freely and widely in the community. The onset of the disease at this time of life may be due to the exacerbation of old latent primary lesions or to the progression of those recently acquired.

**The Early Lesion** Characteristically the first recognizable lesion of tuberculosis of the lungs is parenchymal usually a bronchopneumonic focus which can be noticed in the roentgenogram because it casts a shadow approximately 10 cm. more or less in diameter. Before this size is attained as Medlar has shown the lesion probably has undergone some caseation sloughing and local bronchial extension which may have occurred within a few weeks or months or perhaps at a much slower rate interrupted by periods of latency or retrogression. This inapparent evolution is not apt to produce symptoms although if it is a result of recently acquired primary infection the rather rare occurrence of *erythema nodosum* is sometimes reported. Extension to the pleura may occur early even before the lesion is detectable on the roentgenogram followed by fibrinous or serofibrinous pleurisy.

**Progression of the Lesion** The early lesion having already progressed unseen is likely to progress further especially in young patients. If it does so it is usually by further caseation sloughing ulceration and bronchial dissemination. The variety of progressions is infinite and only a few will be mentioned. Most often the process is rather slow and there will be a series of small extensions of the disease in one or both lungs. The clinical course is *insidious*. As sloughing occurs into the bronchial tubes the purulent discharge mixes with bronchial mucus and the patient may have a slight cough usually in the mornings with scanty mucopurulent expectoration. Examination of the sputum will often reveal the presence of tubercle bacilli. After such ulceration bleeding may occur but in the early phases this seldom causes more than "streaking" of the sputum. The extensions in the lungs cause some toxicity but this too is not usually severe. During a subsequent latency or even partial healing of the lesions these vague symptoms may all subside to add to the deception of the victim. In such ways the disease may

progress and subside from time to time until both lungs are widely involved.

**Acute Exacerbations** Acute exacerbations of pulmonary tuberculosis are explained by similar mechanisms and are symptomatically acute because of the suddenness and severity of bronchial dissemination. The parenchymal focus after caseation and liquefaction may empty rather abruptly into the bronchial tree a quantity of pus highly charged with tubercle bacilli. This is readily inhaled into healthy alveoli. The irritating effects of the pus together with the massive infection give rise to an intense inflammatory reaction manifested as subacute or acute *tuberculous pneumonia* usually of a confluent lobular distribution. In some cases particularly in patients of low resistance this goes on to *acute caseous pneumonia*. These acute forms are almost always related to a preexisting pulmonary lesion as stated but occasionally are caused by analogous mechanisms following the rupture of a caseous tracheo-bronchial lymph node into a bronchus. The acute inflammation often produces profound toxicity. Such exacerbations may follow within twenty-four hours after a hemoptysis obviously explained by the inhalation of blood issuing from a cavity and washing tubercle bacilli with it. This *acute post-hemorrhagic tuberculous pneumonia* is usually in one or both lower lobes and may mark the transition from a limited disease with a single cavity into rapidly progressive and fatal bilateral disease.

**Chronic Fibroid Lesions** Chronic fibroid pulmonary tuberculosis is seen most often in elderly people whose lungs bear the scars of repeated battles with the bacillus. The disease may have spread steadily but very slowly or in a series of exacerbations with long intervals of quiescence. Areas of fibrosis may reflect good healing tendencies but as a rule there are other areas in which cavities and necrotic foci persist in spite of this. With fibrosis goes emphysema, pleural adhesions, flattenings and immobilizations of the chest wall and retractions of the mediastinum. Thus the elderly consumptive may outlive his contemporaries.

**Onset of Pulmonary Tuberculosis** As indicated in the preceding paragraphs the mode of onset varies greatly according to the susceptibility of the patient and the behavior of the pulmonary lesions. Commonly the first manifestations lag behind the actual appearance of the lesions and this *subclinical interval* may be short or long.

*Acute tuberculous pneumonia* may pro

of regimens of drugs to be given concomitantly. The combination of streptomycin 1.0 gm daily and isoniazid 200 mg daily is recognized by the British Research Council to be superior in most respects up to a period of three months. If prolonged this regimen involves the possibility of developing bacterial resistance to both of these more potent drugs. Many physicians prefer holding one in reserve for possible future needs. Also this dosage of streptomycin may be toxic for some patients and the isoniazid dosage is low by United States standards. The usual isoniazid dosage in the United States is 300 to 400 mg each day or 5 to 6 mg of the drug per kg of body weight. A regimen of isoniazid and PAS is well tolerated by most patients and in cavitary cases of pulmonary tuberculosis has been found somewhat more effective than a regimen of isoniazid daily and streptomycin twice weekly. Streptomycin twice weekly and PAS daily is still less effective. Kass and his co-workers at the National Jewish Hospital (1957) espouse a concept based largely on the observations that certain antimicrobial drugs are most effective *in vitro* while tubercle bacilli are actively multiplying and that 8 to 16 mg of isoniazid per kg of body weight per day is desirable in most cases to ensure maintaining an adequate concentration of drug in the blood. They found the most satisfactory regimen to be 15 to 30 mg of streptomycin per kg per day for ninety days or longer if the sputum still contained tubercle bacilli and the daily high isoniazid dosage for eighteen months thereafter. Bed rest was not employed unless the patient was toxic. This regimen has not yet been widely adopted mainly because of the satisfaction many have had with smaller doses.

When resistance to isoniazid, streptomycin and PAS or any two of them develops and the disease is not satisfactorily arrested, recourse often has to be made to other regimens, most of which are less potent and more limited because of their toxicity. Examples of these second defense regimens are mentioned above.

The use of corticotropin and adrenocorticosteroids in the therapy of tuberculosis has received increasing attention. Early after the introduction of these hormones for the treatment of rheumatoid arthritis and other nontuberculous conditions, reports of the aggravation or reactivation of accompanying tuberculosis, usually in the lungs, appeared. Experimental evidence indicated that resistance to tuberculosis as well as other infections may be lowered. Further

studies, however, have shown that this may not become manifest if such treatment is used only as an adjuvant of effective antituberculous chemotherapy. Then the hormone effect may be strikingly and rapidly helpful. Although the indications for the use of these hormones are not clearly defined, they have been broadly outlined by the Committee on Therapy of the American Trudeau Society (1957). It is generally recommended that the hormones should not be used if satisfactory results can be expected with other treatment. Situations in which they may be indicated include tuberculous meningitis with coma, acute and advanced forms of pulmonary disease with overwhelming constitutional symptoms, severe generalized miliary tuberculosis and severe and acute exudative involvement of the serous membranes and also in cases of severe and refractory hypersensitivity to the antituberculous drugs. Quoting the report of the Committee:

The optimal duration of hormone therapy varies. The usually recommended initial dose of 80 units of corticotropin gel, 300 mg of cortisone per day or equivalent doses of corticotropin zinc hydrocortisone or prednisone should be reduced as early as possible but may be required for as long as two or three weeks. It may be necessary to continue a smaller maintenance dose for three or four months or even longer. The size of the maintenance dose should be the minimal amount necessary to maintain control as determined by frequent attempts at reduction of dosage.

It is emphasized that the hormones should not be employed in cases in which the antituberculous therapy is known or suspected to be ineffective because of the presence of drug resistant strains of tubercle bacilli.

#### TUBERCULOSIS OF THE LUNGS

Viewed in broad perspective, pulmonary tuberculosis is the form dominating all others. To epitomize the lung is the usual seat of the primary lesion and later if the primary heals, of the reinfection lesion, the pulmonary lesion is the common source of bronchial and other "intracanalicular" dissemination of the infection and also of hemic dissemination leading to generalized disease. Pulmonary tuberculosis is numerically far in the lead of all other forms as a cause of death, epidemically the pulmonary lesion is paramount because it is usually the source from which the tubercle bacillus is passed through the community.

**Development and Clinical Course.** The rather abrupt rise in the occurrence of pulmonary tuberculosis in adolescence and

toxicity increases its effects become manifest earlier in the day and the patient may even notice that on awaking his vigor and energy are not restored. In progressive disease the languor grows finally into a profound weakness and exhaustion.

*Loss of weight and impairment of tissue tone* are also common. At the true onset there may be no loss and a few patients even report gaining when their disease is first discovered. The loss is usually gradual at first and may amount to only 4 or 5 pounds during several months. Young people may fail merely to gain at the expected rate. During acute and febrile phases the nutrition suffers much more rapidly and prominently.

*Cardiocirculatory instability* is also a usual symptom and may persist long after the temperature becomes normal. The usual manifestation is tachycardia; the rate is regular and accelerated to 80 or 90 per minute during the early phases and subsequently may be higher. After exertion or excitement the quickened rate does not subside as soon as might be expected. The pulse is soft and the systolic blood pressure may be low frequently 90 to 100 mm of mercury. The circulatory tone may be poor and the patient may complain of clamminess and coldness of the hands or feet; the nails may be bluish. Clubbing of the digits may never develop and only in advanced complicated cases is it occasionally extreme. Malar flushing and other local thermic disturbances are related to fever and vagosympathetic reflexes.

*Digestive symptoms of a vague character* are frequent and due particularly to the toxicity. Severe distress such as dysphagia is not observed unless there is extensive tuberculous involvement of the larynx or pharynx. Anorexia manifested as an indifference to food or a capriciousness of the appetite is frequent but usually corrects itself as the toxicity abates after which the patient even though confined to bed may eat heartily. Vomiting is unusual unless the patient has advanced disease of the lungs and a harassing cough. Intestinal symptoms such as seizures of colicky pain and diarrhea alternating with constipation strongly suggest an ulcerative lesion in the bowel as a secondary complication.

The menarche may be delayed and menstruation may be irregular and scanty but as a rule this is observed only after disease is well established. Amenorrhea is unusual except during the febrile stages. The fertility of tuberculous women is somewhat impaired and in the advanced stages of

the disease spontaneous abortion is not uncommon. A striking observation however is that chronically tuberculous women may bear a number of children. There is little or no impairment of the sexual functions otherwise. During the early and middle stages of the disease neither the libido nor *potentia coeundi* is appreciably reduced.

*Nervous and psychic disturbances* are mild or entirely lacking. In most of the early and moderately advanced and many of the far advanced cases there is no appreciable change and the patient's reactions are normal in the circumstances. Later he may become rather neurotic dependent, introverted and depressed (Schultz). This mood however is usually surprisingly mild considering the discouragement which such a chronic illness often entails. Suicidal tendencies or attempts are most uncommon. Euphoria which once was considered to characterize tuberculosis is not often noticeable except during the late or terminal stages. Toxic psychoses are rare.

*Dyspnea* is not usually an early symptom. Slightly or moderately accelerated respiration may be noticeable during the febrile periods or in more advanced fibroid cases in which there is a good deal of secondary emphysema.

*Cough* is the most common local symptom like others of this class seldom develops until the pulmonary lesion has broken down and ulcerated into the bronchi. In the earlier stages cough is most pronounced when the patient awakes in the morning and is due to irritation of the bronchial mucosa from the accumulated discharges. Occasionally cough is attributed to a reflex from irritation of the pleura and later it may be traced partly to tuberculous involvement of the larynx. At first the symptom is usually slight and is quickly relieved after the small accumulation is cleared from the trachea and larynx. Later especially if pulmonary excavation extends and the discharges increase the symptom may become troublesome interfering with eating and sleeping.

*Expectoration*. During the initial phases of the pulmonary infiltration there is seldom any expectoration except perhaps a little clear glary mucus. Later however expectoration is a most common symptom. Its quantity and frequency are variable. Only a few particles of mucopurulent material may be brought up in the morning by clearing the throat or a few coughs gradually this may increase. In other cases expectoration starts more abruptly and may

duce the first clinical symptoms. This form is uncommon although not rare being observed most often in young people in Negroes and in debilitated old people. A preexisting excavating lesion is almost always present but the patient may not have been impressed with the mild symptoms caused by it. The acute attack may appear to be precipitated by exposure to inclement weather by a common cold by severe sunburn by a hemoptysis or by some trivial influence. The patient may experience chilliness prostration pain in the chest and fever this may rise quickly to  $104^{\circ}$  or  $105^{\circ}$  F and the pulse rate to 100 or more per minute. The breathing is quickened at first (20 to 30 respirations per minute) later becoming labored and more rapid as the lungs become further engorged. It is seldom noisy or grunting. A feeling of congestion in the chest increases and the lips and extremities become slightly or moderately cyanotic. The cough may not be severe at first and may be productive of only a few milliliters of mucopurulent sputum daily later larger quantities of a greenish yellow purulent character appear. Unless hemoptysis occurred just before the onset the sputum usually is not bloody. Because of the type of onset and the signs of lobar or lobular consolidation the picture may resemble closely that of a pneumococcal infection (see Differential Diagnosis). Without proper treatment the course may be rapid ending fatally in two or three months in other cases it settles down to a subacute or chronic pace.

More often the onset is attended by *grippe like symptoms* such as fever weakness fatigue and mild aching in the muscles which subside after a week or several weeks perhaps to recur at intervals when the patient again undertakes exertion. In other cases and this is common there is an insidious unexplained slow loss of weight increasing fatigue and impairment of staying powers. These symptoms continue for weeks or months before the patient is aware of serious difficulty then he may find an afternoon fever of a fraction of a degree to several degrees. The usual rest does not restore his energies he finds his efficiency impaired and he is puzzled by his inability to concentrate on his work. Other patients are disturbed by some particular constitutional symptoms such as sweating at night amenorrhea or anorexia and indigestion. Under any of these conditions it is learned usually that the patient previously has had some cough and expectoration or at least a clearing of the throat

in the morning. Sometimes he will report that there has been a little blood in the sputum at irregular intervals. In other instances hemoptysis may be the initial symptom so far as the patient is subjectively aware and this may consist only of a few spots or streaks of blood in the sputum or free and profuse bleeding. He may find a small amount of blood accumulated in his throat upon awaking in the morning. Pleurisy may cause the outstanding initial symptom of characteristic sharp pain (see Tuberculosis of the Pleura).

Hoarseness dryness and tickling in the throat or other symptoms of acute or chronic laryngitis may be the first to arrest attention. Likewise the pain or discharge of a perianal abscess may be the chief complaint the mild pulmonary symptoms previously having been ignored.

**Symptoms of Pulmonary Tuberculosis.** *Fever.* Usually the temperature is normal or subnormal in the morning the rectal reading sometimes being as low as  $96.5^{\circ}$  or  $97^{\circ}$  F and there may be considerable prostration and weakness. Between 4:00 and 8:00 P.M. the fever reaches its height which in acute cases may be  $105^{\circ}$  or  $106^{\circ}$  F. More commonly in subacute or mild cases it ranges up to two or three degrees above normal. Usually a low or moderate fever recurs each afternoon or evening for some days or weeks and in the advanced case this may continue for many months. During grippelike episodes the temperature may rise to  $103^{\circ}$  or  $104^{\circ}$  F daily for a week or so then gradually subside by lysis until it is normal after several weeks.

*Chilliness* is sometimes a complaint associated with a temperature of  $103^{\circ}$  to  $105^{\circ}$  F especially if this appears suddenly.

*Sweating* is not a feature of early tuberculosis and is not often a symptom except in the febrile and exhausted states. Then it occurs usually at the time of the temperature rise and immediately afterward. In some cases in which there is extensive excavation of the lungs and secondary suppurative infection the sweats are drenching and prostrating.

*Malaise lassitude and fatigue* are the most common symptoms of tuberculous toxicity. At first they are noticed toward the end of the day's activity when the patient may eschew his usual diversions or interests in order to get additional rest. If he is the type to disregard such mild symptoms he may become irritable grouchy and impatient. However the symptoms are not always unpleasant and may be evidenced only as an urge to rest and sleep. If the

**Wheezing and stridulous breathing** are occasionally complaints in cases of cavernous tuberculosis less often in others. The wheezing may be noticeable behind the sternum but more often is localized to one side of the chest and is due usually to distortions or stenosis of the bronchus or trachea caused by tuberculous ulceration, granulomas or cicatrices. Rarely the trachea becomes so filled with edematous inflammatory tissue that suffocative attacks may occur. In old standing fibroid cases wheezing may be referable to catarrhal accumulations in distorted bronchial tubes.

**Hoarseness** may be the result of temporary congestion of the larynx from incessant coughing. Persistent hoarseness, dryness and tickling of the throat are caused often by laryngeal tuberculosis.

**Physical and Roentgenographic Examination in Pulmonary Tuberculosis.** The physical examination of a patient for pulmonary tuberculosis should be thorough and complete. Fluoroscopy is useful and sufficient to visualize changes in respiratory mechanics and gross densities in the lungs. However, the greater accuracy of the roentgenogram must be appreciated particularly in detecting early lesions.

**Physical Examination of the Patient with Limited or Early Pulmonary Tuberculosis.** In the case of a relatively early lesion physical examination reveals no superficial abnormalities or perhaps only slight evidence of anemia and loss of weight. The temperature may be found normal or elevated a fraction of a degree to several degrees, and the pulse may be moderately accelerated. Careful examination of the chest may not reveal abnormal signs or one may detect definite changes such as slight dullness, bronchovesicular breathing and a few persistent crepitant or moderately coarse rales. Rales alone may be found in an area scarcely more than 10 or 20 cm. in diameter. The roentgenogram as a rule reveals evidence of the lesion more precisely as a soft cloudy mottling often associated with small honeycombed areas of rarefaction or larger round zones of similar translucency which represent cavities (see Fig. 29). In frequently in the case of a small tuberculous lesion the roentgenographic findings are negative or indeterminate while definite rales may be heard in a given spot. Oblique roentgenographic views or other special views then may reveal the mottling or rarefaction which in the customary posteroanterior view was concealed by the interposed density of the heart or some other structure. These evidences of the le-

sions are usually disclosed in the upper third of one lung not infrequently beneath the level of the clavicle but sometimes exclusively above it. Signs of similar or different intensity and variety may be detected sometimes in both lungs. These may be located on one side in the upper third and at the apex of the opposite lung or there may be other variations such as apical signs on one side and basal signs in either one of the lower lobes. In a few cases the signs are limited to the middle or lower part of the interscapular region on one side occasionally even below this level. In some the original apical lesion is so slight as to give no definite signs either by physical or roentgenographic examination while the obviously secondary lesions are easily detected.

**Long standing and fibroid lesions** may betray their presence through the changes due to retraction and shrinkage of the fibrous tissue. Thus a rather limited depression of the clavicular fossae on one side, slight or moderate atrophy of the muscles in this region, limitation of motion of the ribs and deflection of the trachea give the main clue to the long duration of the lesion. Isolated nodular fibrotic or calcified lesions such as those of the primary complex usually are not detected by physical examination but cast characteristic dense sharply circumscribed shadows in the roentgenogram.

**Physical and Roentgenographic Signs of**

FIG. 29. Recently developed tuberculous lesion in right lung. Moth-eaten appearance of density in second anterior interspace suggests softening and excavation.

soon amount to one ounce or so in a day. In any case with progressive pulmonary excavation the quantity usually increases until 30 or 60 ml are produced each day, mainly in the morning. In advanced cases 300 to 350 ml may be brought up daily. The sputum is not foul except in the unusual case in which secondary anaerobic infection develops in the bronchi or pulmonary cavities. When expectoration is slight the flecks of pus are seen in the clear mucus. In caseous pneumonic cases particularly at the start of excavation the sputum is purulent and of a greenish yellow color but later this usually becomes yellow and the admixture of mucus is noted. In more chronic cases the mucopurulent material is of a coherent, sometimes tenacious character. The sputum on standing retains its homogeneous mucopurulent character and does not separate into layers. The quantity and the character of the expectoration reflect to some extent the changes occurring in the pulmonary lesions. A daily production of 30 to 60 ml of purulent green matter speaks for a caseous pneumonic liquefying lesion. A change to yellowish, more mucoid sputum suggests a subsidence of the ulcerative process indicated further by a diminution of the amount and a continuing decrease of the purulent element. Sudden and marked variations in the quantity of the sputum may be due to bronchial occlusion.

**Hemoptysis.** Blood spitting occurs in more than one half of all cases of untreated pulmonary tuberculosis. As a rule the quantity is small, consisting of streaking, spotting, or pinkishness of the sputum in the mornings, but copious bleeding is not rare. Hemoptysis usually is due to the ulceration or weakening and rupture of the walls of the vessels in tuberculous cavities. Infrequently in chronic healed cases it may be traced to the mechanical rupture of superficial vessels in the walls of distorted bronchi. An ulcerative lesion in the trachea or bronchus also is an infrequent cause. As a rule the symptom is obviously not an indication of early disease. Bleeding may start at any time during the day or night but has been observed more frequently in the early hours of the morning. Exceptionally it is induced by a violent straining effort or by trauma. Staining or streaking of the sputum may occur without other sequels but in other cases is a precursor of more copious hemoptyses. Frank hemoptyses however appear most often without forewarning. In women there may be a definite relationship with menstruation

and a few have recurrent hemoptyses monthly. During the bleeding the patient may notice boiling or bubbling sounds in his chest localized to one side or to the center. The blood may be raised easily or may flow so freely as to cause severe choking, coughing and gagging.

Immediately fatal hemoptyses occur only in a small minority of the cases, usually of longstanding fibroid cavernous tuberculosis in which vascular granulation and connective tissue have proliferated in the cavity walls, a vessel may undergo gradual aneurysmal dilatation (Rasmussen) until it finally gives way. As a rule however a single hemoptysis amounts to 30 or 60 ml, occasionally to as much as 300 ml. The bleeding is then usually arrested by the deposition of a clot at the site of the vascular rupture. Dark clots may be expectorated for several days, sometimes in the form of bronchial casts. This may be the end of it but there may be a few or many recurrences at intervals of hours, days or longer periods. Then the loss of blood may cause anemia. The patient may become nervous and frightened or may go into mild shock with fearfulness, pallor, coldness of the extremities, tachycardia and weakness and sometimes sweating. Vomiting may occur soon after, especially if the patient has swallowed much blood. Within a day or two there may be a rise in temperature of several degrees, usually traceable to the aspiration of blood into the lower lobes of the lungs. The resulting tuberculous pneumonia has been described in previous paragraphs.

**Pain in the chest** is usually a symptom of inflamed pleura. It may be an early complaint, therefore, if the initial pulmonary infiltration is situated close beneath the pleura, facilitating such secondary extension. In cases associated with chronic adhesive pleurisy, a dullness, heaviness, soreness and aching of the side is a common complaint and is particularly noticeable during fatigue and during cold, damp weather. Such sensations may be noticeable for many years after all activity of the lesions has subsided. A sudden stabbing pain in one side or behind the sternum followed immediately by shortness of breath and other manifestations is usually indicative of collapse of the lung and acute pneumothorax. Persistent or recurrent localized pain may be referable to tuberculous lesions of the spine, costal cartilage or sternum, less often of the ribs or sterno-clavicular joints; these may be associated with superficial swelling and redness.

**Blood Cell counts** estimation of the hemoglobin and the erythrocyte sedimentation rate are used routinely in clinical practice. Interpreted in combination with other data they are valuable in diagnosis and in following the course of the disease (See *Changes in the Blood of Tuberculous Patients* p 254).

**Urine** In febrile tuberculosis the urine commonly shows slight traces of albumin. Protein loss through the kidney may become marked after amyloid changes have occurred. From the results of animal experimentation it has been suggested that tubercle bacilli free in the blood stream may be excreted through the intact and normal kidney and then may be discovered in the urine (excretory bacilluria). In human beings however experience indicates that this must be a rare happening and the discovery of bacilluria is taken as presumptive evidence of a tuberculous lesion in the urinary tract or the genital organs. The discovery of pus cells and an abnormal number of erythrocytes or persistent albuminuria in a patient with pulmonary tuberculosis should always lead to a further investigation for the presence of a renal lesion.

**Pleural Fluid** In some cases of pulmonary tuberculosis complicated by a pleural effusion the discovery of tubercle bacilli in the aspirated fluid may verify the diagnosis when this evidence is lacking on account of negative tests of the sputum.

**Basal Metabolic Rate** In afebrile cases of pulmonary tuberculosis this is normal unless there is some independent cause for variation. In febrile cases the rate is elevated according to the degree of fever.

**Respiratory Function** In the presence of limited lesions the respiratory function is not materially disturbed. In later stages functional impairment may become severe because of the invasion and destruction of pulmonary parenchyma and shrinkage of fibrous tissue in the lung and the pleura and the associated retraction of the heart and distortion of bronchi and blood vessels. Secondary emphysema may also be a serious functional handicap. The degree and significance of the impairment may be determined with considerable accuracy by the separate measurement of ventilation, the mixing of gases in the lungs, the adequacy of exchange of gases between the alveoli and the pulmonary capillaries and the efficiency of the pulmonary circulation. By using the bronchspirometer some of these measurements can be made separately for each lung. The tests are needed

in certain cases to help determine the patient's probable tolerance of surgical procedures such as pulmonary resection.

### *Diagnosis of Pulmonary Tuberculosis*

Tuberculosis should be considered as a possible cause (a) in any patient who presents vague symptoms of loss of weight, malaise and easy fatigue particularly when this is associated with persistent cough (b) in any patient particularly a young person who has recurrent or prolonged attacks simulating grippe or influenza (c) in any patient who has atypical or unresolved pneumonia (d) in any patient who has cough and expectoration persisting for more than several weeks even though there may be little or no impairment of the general condition (e) in any patient who spits blood (f) in any patient who has pleurisy especially with effusion (g) in any patient with a persistent unexplained fever (h) in any patient with other mild or obscure lesions such as persistent lymphadenopathy, fistula in ano and chronic laryngitis giving rise to chronic hoarseness. The diagnosis then depends particularly upon physical, roentgenographic and laboratory examinations. In such circumstances the finding of a lesion usually in the upper half of the lung which gives the characteristic roentgenographic appearance of an infiltration or fibrosis with or without cavity and with or without demonstrable physical signs such as rales warrants the presumptive diagnosis of tuberculosis. If there is no demonstrable cavity and no sputum the diagnosis is confirmed by a period of observation during which the lesion persists or gradually changes. Cultures of gastric fluid may grow tubercle bacilli. If excavation is demonstrated or suggested by the other examinations the diagnosis should be verified by the finding of tubercle bacilli in the sputum. The failure to find bacilli in a case in which there is moderate or fairly copious mucopurulent sputum weighs heavily against the diagnosis of tuberculosis. The finding of tubercle bacilli in the discharges or material obtained from other lesions such as pleural effusion or pus from a tuberculous fistula strongly suggest that the pulmonary lesions are also tuberculous. The finding of rales in the upper third of the chest in a case in which the roentgenogram shows no parenchymal change and in which the sputum test is negative for tubercle bacilli leaves the diagnosis in doubt and raises the question whether the lesion is nontuberculous. The finding of physical and roentgenographic signs exclu-

**Advanced Lesions in Pulmonary Tuberculosis** There is no limit to the variety of signs which may be produced by extensive tuberculosis. If the disease remains confined chiefly to one lung this may be converted into a fibrous shrunken mass with a variety of secondary effects such as flattening and immobilization of the hemithorax, atrophy of the muscles and skin on this side, inequality of the pupils from involvement of the sympathetic ganglia, flushing of one cheek from a similar cause, dilated superficial venules of the skin of the chest, marked deflection of the trachea and retraction of the heart. The roentgenogram may show a shrunken and opaque lung and the retractions associated with it while physical examination may reveal dullness to flatness, bronchial and amphoric breathing, post-tussive suction, widely distributed rales and many other classic signs. In the case of advanced bilateral fibroid nodular tuberculosis, secondary emphysema may be conspicuous and the physical signs of this together with few rales may leave one in doubt until the roentgenogram shows the typical distribution of nodular and streaky shadows throughout both lung fields.

Extensive bronchopneumonic or pneumonic lesions which have not existed long enough to produce such secondary changes give rise most constantly to widely distributed rales which vary from the crepitant quality in the early stages of infiltration to moderately coarse bubbling and consonating rales after the lesions have caseated and undergone liquefaction and ulceration. With these are discovered varying signs of solidification and excavation depending on the concentration of the lesions in a given lobe and their state of degeneration. Physical signs then may be more informative than the roentgenogram since in the latter the opacity may be so complete that detailed structure can no longer be made out. Smaller bronchopneumonic lesions however are usually depicted more faithfully by roentgenographic than by physical signs. In all these situations the findings may be associated with or modified by changes in the pleura or other adjacent structures. A large pleural effusion may obscure pulmonary lesions while more chronic pleura changes may be well revealed by peripheral densities and retractions which stand out in contrast with the air bearing lung.

Tomograms (planigrams, laminograms, selectoplanes) are helpful to supplement conventional roentgenograms especially in

defining more precisely the composition and location of individual lesions.

Complete examination of the body may also bring to light changes outside the thorax. Thus the discovery of an inflammatory thickening of one vocal cord or a phlyctenule in the conjunctiva or a nodule in the epididymis or of a fistula in ano may be most important factors in constructing the complete picture of the disease.

**Laboratory Findings in Pulmonary Tuberculosis**  
**Sputum** Proper collection and examination of the sputum are most important. There may be none if the pulmonary lesion has not ulcerated. Even after ulceration has occurred the quantity of discharge may be so small that the patient is not aware of it and unconsciously may swallow it. In this case he is carefully instructed to collect in a suitable container any slight discharge appearing in the throat particularly in the mornings. If he is unable to produce a satisfactory specimen the *fasting stomach contents* are aspirated with a stomach tube when the patient first awakes in the morning. This specimen is treated by centrifugation, neutralization and inoculation on suitable cultural medium. **Laryngeal smears** have been used to recover small mucopurulent discharges for examination; this is quick and convenient but not to be relied upon if no acid fast organisms are demonstrated. **Bronchial lavage** (introducing 20 ml of warm saline solution into the trachea and then collecting the expectorated material for examination) has been advocated but is not to be recommended because of the hazard of bronchial dissemination of the infection. Occasionally bronchoscopic specimens contain demonstrable bacilli when expectorated material does not. Organisms may also be found in the feces.

Ordinarily the patient with a pulmonary cavity will be able to collect mucopurulent material upon awaking in the morning and this is the specimen needed. Occasionally bloody specimens or the blood from a hemoptysis will be suitable for examination. A great many elements may be searched for such as elastic fibers, various types of cells, secondary organisms and albumin but these have only subsidiary value unless some special point is to be determined. The most important items are an estimate of the character and daily volume of the sputum and an effort to detect tubercle bacilli in it. (See Demonstrating the Tubercle Bacilli, p. 253.) Appearance, consistency, possible layering and odor are noted.

usually can be made in the space of a relatively few days. Acute bronchopneumonia due to organisms such as *streptococci* or *anaerobic bacteria* which commonly goes on to abscess formation may be confusing because of the pattern of the pulmonary lesions simulating tuberculosis. The acute onset often with chills the leukocytosis the finding of an abscess or cavity and the failure to demonstrate tubercle bacilli in the sputum are presumptive evidence against the tuberculous nature of the disease while a great predominance of other specific organisms may give the real clue. One must be certain however that common pyogenic organisms are not merely contaminants from the mouth.

Foulness of the sputum shortly after the acute onset of the disease always speaks for *putrid lung abscess*. In longstanding cases of chronic lung abscess a cavity or fibrotic lesion may be discovered in the upper part of one lung and this may give rise to suggestive symptoms such as hemoptysis. The history of onset particularly the history of fetid expectoration and the failure to demonstrate tubercle bacilli usually indicate the diagnosis.

When tuberculosis is suspected as the cause of a *protracted and obscure fever* the failure to find a pulmonary lesion is presumptive evidence against this diagnosis but it may be necessary still to exclude the presence of tuberculosis of other organs. The same is true in any chronic debilitated state in which tuberculosis may be suspected.

*Bronchiectasis* not infrequently must be differentiated in patients who give a history of chronic cough possibly with foul and bloody sputum. The lesion is usually in the lower lobes but occasionally is apical. Rales may be heard but the roentgenogram fails to show the typical tuberculous infiltration and excavation and instead there may only be strandlike densities suggesting interstitial or peribronchial fibrosis. Thus and the absence of tubercle bacilli from the sputum suggest bronchiectasis which may be verified by the use of bronchography with iodized oil.

*Cancer of the lung* simulates tuberculosis because of the chronic cough expectoration of pus and blood febrile episodes and gradual wasting. Physical and roentgenographic findings are more likely to be those of a bronchial lesion causing localized wheezing rhonchi or of suppurative pneumonia secondary to the bronchial occlusion. The failure to find tubercle bacilli in the purulent sputum is most important

Bronchoscopy the biopsy of a superficial metastatic lesion in a lymph node or the finding of other internal metastases may be diagnostic.

Special cytological studies may reveal cancer cells in the sputum and this may be a crucial finding in the case of peripheral roentgenographically spherical lesions too distant to be reached by the bronchoscope. Such a density on the roentgenogram is also consistent with some benign tumors and with certain caseous or fibrocaceous lesions ("tuberculoma"). In doubtful cases of potentially serious import surgical exploration by thoracotomy may be indicated.

*Pulmonary fibrosis* and *emphysema* may have to be differentiated because of symptoms and because tuberculosis particularly the chronic disseminated form sometimes is a cause. Chronic cough occasional blood spitting and increasing weakness may be particularly suggestive. In tuberculosis the fibrous changes are usually associated with calcifications identified by roentgenography. Extrapulmonary lesions may also be found especially in the lymphatic system or in the abdomen. The history of some other possible cause such as chronic paranasal sinusitis or exposure to injurious dust may give the proper clue. In *silicosis* the nodular noncalcareous roentgenographic appearance of the lesions evenly distributed in both lungs particularly in the central portions is characteristic. Association of tuberculosis with silicosis a not infrequent finding may be suspected when there are confluent roentgenographic shadows in addition to nodular ones.

There is a sizable category of nodular and stringy lesions revealed best in the roentgenogram which may simulate tuberculosis of a disseminated distribution particularly that due to hemic dissemination. In addition to silicosis this group includes sarcoidosis metastatic carcinosis and unusual or rare lesions such as the pulmonary granulomatosis of beryllium workers and those associated with scleroderma tuberous sclerosis and primary amyloidosis. Chronic pneumonia due to the inhalation of mineral or other oils may give a confusing picture but is more likely to be unilateral confluent and limited than widespread.

*Mycoses* may produce changes simulating tuberculosis but these are unusual. The lesions may be of a subacute bronchopneumonic or chronic granulomatous and fibrous nature and the pattern in the roentgenogram may simulate tuberculosis closely even to cavity formation. In a pa-

FIG 30 Tuberculous cavity in the right lower lobe at the level of the eighth rib posteriorly. Exudative infiltrate in the middle of the left lung represents a bronchogenic extension from the cavity.

sively in the lower half of the chest does not exclude tuberculosis as a cause but if in addition there is mucopurulent sputum devoid of tubercle bacilli tuberculosis as a rule can be excluded. In doubtful or difficult cases the tuberculin test may be valuable especially if negative.

Modern methods of tuberculosis case finding among apparently healthy people afford another approach. Among each group of 1000 adults thirty years of age or older routine roentgenographic examination of the lungs reveals active tuberculosis in one or two individuals; the rate is even higher in certain groups such as elderly people admitted to hospitals for the treatment of some other condition. Because of the lower incidence of tuberculous infection among young people, especially children, and the desirability of avoiding unnecessary exposure to radiation at this time of life, tuberculin testing is recommended. The chests of positive reactors then should be examined by roentgenograms and if necessary by other procedures as well. Among "negatives" no further examination is usually necessary although it is advisable to repeat the tuberculin test at intervals of a year or two to detect the possible acquisition of a primary infection. Aside from the finding of obviously active disease, many adults (10 or 20 per cent) will be discovered bearing pulmonary le-

sions due apparently to inactive tuberculosis or to some other cause. Some of these require study to determine the import of the lesions and the correct etiological diagnosis.

**Differential Diagnosis of Pulmonary Tuberculosis** The approach to differential diagnosis varies according to the presenting findings. Thorough and careful study of the case usually enables one to arrive at a definite conclusion.

In a patient in whom unexplained fever develops and who is discovered to have a pneumonic lesion without demonstrable excavation, distinction often has to be made between early tuberculosis and simple bronchopneumonia, especially if the lesion is confined to an upper lobe. Demonstrably rapid changes in the lesions within a few days or a week and failure to find tubercle bacilli usually identify bronchopneumonia as such, while the failure of the lesion to clear in the expected time favors tuberculosis. Similar distinctions are of value in the differentiation of eosinophilic infiltrates of the lung, sometimes representing bronchopneumonia in a patient who gives a history of asthma or other allergy; the eosinophils of the blood may rise to 25 per cent or more of the leukocytes.

In viral pneumonia the pulmonary lesions sometimes may fail to resolve completely before several months have elapsed as indicated by persistent shadows on the roentgenogram and rales. The acute onset and course, the absence of pulmonary cavity, the failure to demonstrate tubercle bacilli and the gradual and complete resolution of the lesions even if delayed exclude tuberculosis. Occasionally acute caseous pneumonia occupying a large part of the lobe or lung may be confused with pneumococcal lobar pneumonia, and the confusion may be increased by the finding of pneumococci of a higher type in the sputum. While in a rare case of tuberculous pneumonia the leukocytes of the blood may rise to 20,000 per cu mm, the count seldom attains the height commonly seen in lobar pneumonia, nor is there often such a pronounced relative increase of the polymorphonuclear neutrophils. Since caseous pneumonia usually represents an acute confluent bronchopneumonic extension from a tuberculous cavity, tubercle bacilli will be found on careful search of the sputum, which as a rule is not rusty although it may be bloody. In caseous pneumonia the signs of cavity may be detected on physical and roentgenographic examinations. If not immediately the diagnosis

most always do well under suitable treatment. In such cases the life expectancy is equal almost to that of groups of similar age in the general population. The more extensive the pulmonary lesions, the greater is the future hazard. Before the advent of chemotherapy patients with far advanced cavitary disease had an average life expectancy of two to five years and about a third of those in the moderately advanced stage were dead within five years. Chemotherapy has vastly improved the lot of such patients in prolonging life and raising the chances of satisfactory arrest of the disease. However, such benefits are far outweighed by the advantages of an early diagnosis.

Under treatment which includes appropriate chemotherapy it is only the exceptional patient who does not show some favorable response. The subsidence of symptoms is often rapid and striking and the early resolution of the exudative inflammatory components of the lesions may be most impressive. A state of well being may be achieved rather soon and this can be deceptive—the false recovery—which was recognized by Laennec and many who followed him. At this point and later the crux of the prognosis rests in the expected persistence in the body of living tubercle bacilli, the likelihood of their permanent confinement anatomically and the biological factors of vital resistance which when sufficient restrain or prevent bacterial multiplication and thus avoid a recrudescence of the disease. The multiplicity of choices of regimens of chemotherapy which are now available and the avenues of management which these have opened through the medium of surgical resection and other manipulations have completely changed the view of prognosis. Formerly this was based on extensive statistics relating largely to the natural course of the disease and pointing to the grim conclusion that while the course could often be slowed or halted by rest treatment and a mode of life keyed to the handicap, eventual death from slow progression or final flare up was to be expected in most cases. Even then, however, the prognosis of the minimal case detected early after its inception and treated with understanding and care was excellent. Today many of those ominous clinical portents of a decade ago need not hold. Swift death from meningitis, generalized milary disease and *phthisis florida* can be averted and the possibility of permanently arresting pulmonary cases has been vastly extended. Already many recovered or improved patients

formerly rated as lost have lived to die from other unrelated causes while some have succumbed to the syndrome of cor pulmonale because of the remarkable scarring of extensively diseased lungs. Although sufficient time has not yet elapsed to determine the rate of relapse and the final outcome of many cases treated by current methods, certain factors may be mentioned which have an important influence.

The character and pathological anatomy of the lesions are of great significance. Accumulations of inflammatory exudate which have not undergone necrosis are capable of resolution and this is observed in most cases of pneumonic tuberculosis. However, these are almost always a part of a lesion which is necrotic and caseous at or near its center; the latter generally is incapable of resolving and constitutes much or most of the residual lesion after resolution has been completed. Tubercle bacilli usually disappear from the areas in which resolution has occurred but they survive in necrotic areas of caseation, abscess and cavitation; healing then depends mainly on fibrosis. In the lungs, single or several isolated caseous residues of 1.0 or 2.0 cm. in diameter usually become more or less encapsulated with fibrous tissue under continued chemotherapy and the rate of relapse up to five years appears to be less than 5 per cent. Larger lesions of this type are more liable later to liquefaction and excavation leading to an exacerbation of the disease and this is particularly true of massive caseous pneumonia. Pulmonary cavities several centimeters in diameter frequently become dry and relatively clean and then under continuing chemotherapy may be closed by the shrinkage of fibrous tissue laid down in the walls. Tubercle bacilli disappear from the sputum (the "closed negative case") and the outlook for permanency of healing is excellent. Large cavities usually do not close completely. As they persist, some may continue discharging tubercle bacilli (the open positive case); a sign of active infection threatening progressive invasion of the lungs; others dry out as the walls are partly transformed into fibrous tissue and tubercle bacilli are no longer demonstrable in the sputum (the open negative case). Among 475 patients followed up to five years and reported by J. W. Raleigh (1957), the relapse rate in the "closed negative" cases was about 18 per cent, in the open negative about 40 per cent. The open negative case is a unique product of chemotherapy since before its advent a

tient suffering with a chronic cough ex-  
pectoration and general ill health failure  
to demonstrate tubercle bacilli and the find-  
ing of specific fungi in the sputum by  
microscopic or cultural examinations may  
settle the diagnosis other tests used in-  
clude the serum antibody titer skin sensi-  
tivity tests and virulence of the organisms  
for animals It is important to know  
whether there has been an opportunity for  
infection with fungi and whether there  
have been systemic lesions

In the desert section of southwestern  
United States infection with *Coccidioides  
immitis* is fairly common and in a few of  
those infected acute pneumonic lesions de-  
velop some with excavation In less than  
1 per cent of those infected the disease  
becomes generalized and fatal The coc-  
cidioidin skin test serological and bac-  
teriological findings and the usually short  
clinical course are diagnostic features  
*Histoplasmosis* also has been identified as  
a cause of chronic pulmonary lesions which  
may be followed by calcification particu-  
larly in the eastern central part of the  
United States Testing with histoplasmin  
for sensitivity of the skin and the use of  
the specific complement fixation test are  
important aids in diagnosis Other mycoses  
found more often in rural than in urban  
populations which may involve the lungs  
and simulate tuberculosis include actino-  
mycosis blastomycosis and cryptococcosis  
It is always important when fungi are  
found in the sputum to determine whether  
these are implicated in the pulmonary dis-  
ease or are merely nonpathogenic inhabi-  
tants of the mouth In the great majority of  
cases the diagnosis uncertain at first re-  
solves itself into that of tuberculosis

Since in the United States and many  
other countries tuberculous infection early  
in life is no longer almost a universal  
phenomenon the value of the tuberculin  
skin test as an easy and reliable aid in  
differential diagnosis has been greatly en-  
hanced in most questionable cases a nega-  
tive test affords strong evidence against  
tuberculosis In the presence of etiologically  
obscure pulmonary disease which appears  
to be clearly or possibly of a disseminated  
or chronic infiltrative or granulomatous  
nature it is customary now in some areas  
to perform the tuberculin test simultane-  
ously with the coccidioidin and histoplas-  
min tests in the hope of expediting the  
diagnosis In more difficult and urgent situ-  
ations the examination of specimens re-  
moved by biopsy from tributary lymph

nodes the liver the bone marrow or even  
from the lung itself may be indicated

*Pulmonary lesions secondary to cardiac  
disease* sometimes create a confusing pic-  
ture The hemoptysis of mitral stenosis  
may be misleading at first because of the  
finding of rales and roentgenographic  
changes suggesting fibrosis and infiltration  
of the parenchyma Demonstration of the  
cardiac lesion the failure to demonstrate  
a cavity the lack of sputum containing  
tubercle bacilli and the distribution char-  
acter and behavior of the lesions lead  
correctly to the conclusion that the lesions  
are due to secondary fibrosis from conges-  
tion and stasis (associated in exceptional  
cases with *hemosiderosis*) or to infarction  
or edema A pleural effusion clouding the  
picture may be found related to the same  
cause Rarely a pulmonary infarct may  
become secondarily infected and break  
down to form an abscess simulating a  
tuberculous cavity

*Suppurative lesions* in other structures  
which may become connected with the  
lungs must be distinguished Thus chronic  
pleural empyema which has ruptured into  
the lung may cause many symptoms com-  
mon to pulmonary tuberculosis and the  
same may be said of chronic hepatic or  
subphrenic abscess which has perforated  
through the diaphragm into the lung A  
searching history of previous illnesses and  
operations and failure to demonstrate  
tubercle bacilli in the sputum usually elimi-  
nate tuberculosis

*Unusual conditions* such as Hodgkins  
lymphoblastoma invading the lung from  
the mediastinum esophagotracheal fistula  
dermoid or parasitic cysts which have rup-  
tured into the lung and aortic aneurysm pro-  
ducing bronchial stenosis by pressure may  
necessitate excluding tuberculosis because  
of the symptoms of chronic pulmonary dis-  
ease The clinical history the failure to  
find tubercle bacilli and the demonstration  
of other lesions especially in the media-  
stinum exclude tuberculosis as a rule and  
suggest the proper diagnosis

**Prognosis of Pulmonary Tuberculosis** A  
favorable outcome is best assured by the  
detection of the disease in its early phases  
the administration of proper treatment and  
the continuation of this procedure until  
healing processes are well established and  
a solid balance of vital resistance can be  
assumed to exist There is a definite cor-  
relation between the extent of the lesions  
and the ultimate prognosis Early "mini-  
mal lesions without cavity formation al

tion once every six to twelve months to detect possible instability. Others of less certain status especially if the lesions are suspected to be poorly fibrosed, partly necrotic and possibly honeycombed with minute cavities should be studied more thoroughly with all available diagnostic procedures including cultures of the sputum and gastric fluid to determine whether active treatment is needed. Some of these patients benefit by a period of hospitalization for this intensive study. This may clarify the situation and justify allowing some to continue an active life under the watchful eye of a physician. Others who have vague symptoms of undue fatigue and loss of weight may be assumed sometimes to suffer mild toxicity from partly healed but unstable pulmonary disease and they may benefit from a period of treatment such a precaution may prevent more serious exacerbations. Some too may have such symptoms from disease in other organs while the pulmonary lesions remain inactive treatment may be indicated on this account.

There is also a group of patients who seem to have developed fairly good resistance and who have unawaredly coped with the disease with some success before a diagnosis is made. Many of these will be found to have partially fibroid lesions containing small cavities and mild symptoms including scanty expectoration containing tubercle bacilli. Trouble is brewing for these patients and their management demands careful judgment. An elderly person may maintain the balance in his favor by limiting his activities under medical treatment but a younger one should have the benefit of more active and radical treatment in view of the prospect of permanent recovery.

Patients with advanced bilateral cavitory disease can be helped at least temporarily with prolonged chemotherapy. Although they have chronic permanently disabling disease to which most of them eventually succumb their lives often may be prolonged and made more comfortable.

*Principles Objectives and Methods of Treatment* Recognizing that tuberculosis of sufficient extent and activity to require treatment has already caused some necrosis and possible excavation of tissue it is appreciated from the start that treatment is a long term proposition. Fairly rapid resolution of exudative lesions may be promoted but the fibrous repair of necrotic residuals requires many months. Since there is no proof that infection can be completely eliminated by the use of drugs or other means

ures the possibility of later recrudescence of the disease must always be considered and treatment should be planned with the aim of averting this. Much time is required not only for fibrous healing of lesions but also to raise the patient's resistance to the infection to the highest possible level. When the diagnosis is made it may be possible to judge approximately the kinds of treatment which are likely to be most effective and to anticipate the probable outcome. However the response varies from one patient to another and valuable information is gained by observing the effects of a chosen regimen during the early weeks and months. In time it is learned for instance whether acute tuberculous pneumonia is to undergo extensive resolution or whether widespread necrosis prevents this and points to the eventual need of surgical resection. Similarly during the early course small exudative lesions in one lung may resolve almost completely leaving a major problem of advanced fibrocavitary disease in the opposite lung which may have to be treated by surgical collapse or resection. At the start the probable duration of treatment though very important to the patient is secondary to a consideration of the result which eventually it is hoped to achieve.

The first objective is to suppress microbial activity and halt the progress of the disease as quickly as possible and especially to stop the destruction of tissue. Once this is achieved fibrous repair can proceed at its maximal rate. All reasonable and necessary measures therefore are adopted. Although in many instances rest treatment alone or chemotherapy alone may act favorably—the former by allowing the natural defenses to function best and the latter by its specific antimicrobial effect—the results are likely to be better if at the start both are employed. The choice and dosage of drugs may vary somewhat according to the severity of the disease and are relied upon heavily to control the infection. Until this is accomplished in the more active cases as indicated by a material reduction of the cough and expectoration and a lowering of fever the patient is kept in bed and given nursing care. Once the symptoms of active infection have subsided and the beginning resolution of the pulmonary lesions is demonstrated it is usually safe to permit him a few liberties such as sitting out of bed for meals and walking to the bathroom and these may be gradually increased. The time for such steps varies greatly. In the acute caseous pneumonic cases several months may pass before the

cavity was virtually synonymous with positive sputum. The formerly poor prognosis signalled by a persisting cavity has been greatly improved but obviously by no means reversed.

The principles implicit in this discussion apply also in other lesions. Ulcers of the skin, larynx, intestine or bladder usually heal durably under chemotherapy partly a credit to their superficial location and the absence of deep enclosed necrotic masses. On the other hand caseous residues of material size in such structures as bone, kidney and fallopian tubes may be smoldering foci which stimulate the formation of fibrous tissue in their environs and may flare up from time to time. Meanwhile under chemotherapy the caseous matter may become inspissated at least temporarily and sinuses leading to the surface from underlying abscesses may close and heal.

**Relapse** when it occurs is almost always related to an exacerbation in one or more of these necrotic residues and the risk depending on so many factors is difficult to forecast. The stress and strain of life operating in devious and largely obscure ways have long been recognized as strong influences. Heavy labor aside from the deleterious effects of attendant excessive fatigue may in a mechanical way stimulate a quickened circulation of blood and lymph in and about a lesion and thus favor its reactivation, liquefaction and extension. By way of contrast patients leading a closely sheltered, strictly routine and quiet life have been known to live for many decades with chronic cavitory disease of the lung or kidney or chronic sinuses draining through the skin—and without chemotherapy. In such cases the sputum or other discharge is usually scanty although it continues to be bacilliferous. One effect of chemotherapy although it falls short of bringing about the closed negative state of lesions is the reduction of exudate and discharge from persisting defects and thus at least helps prevent the spread of infection into healthy parts. Some patients seem to derive such benefit from chemotherapy for a number of years but the duration is limited by the emergence to predominance of drug-resistant tubercle bacilli.

Age of the patient is of interest prognostically although this is offset largely by the use of chemotherapy. During adult life and old age men are at greater risk statistically than women and one may speculate that the difference is related partly to the poorer hygiene of living of the former.

Elderly men have more emphysema and other pulmonary damage from past neglected respiratory infections and occupational exposures such as that to siliceous dust and these help increase their vulnerability to progressive tuberculosis. Some of these men are homeless recluses who show up for treatment only when their disease is far advanced, their resistance depleted and their responsiveness to chemotherapy hopelessly feeble or nil.

**Treatment of Pulmonary Tuberculosis** The need for treatment is usually self-evident when the patient has overt symptoms of active disease. But in addition there is a large category of patients in whom the indications are not so clear-cut. Most of these are brought to notice by routine roentgenographic examinations of the chest. Since the patient with a small active lesion often presents the vaguest of symptoms or none at all the importance of determining its significance cannot be overemphasized. The prompt and proper treatment of these cases yields results far superior to those achieved after more extensive invasion and destruction of tissue have occurred. The problem therefore is to distinguish these cases from those in which apparently healed and inactive lesions are found. It is simplified if certain data from previous examinations are available. An authentic negative tuberculin test within the previous several years is reliable evidence that the newly developed pulmonary lesion is of recent origin, presumably the result of a primary infection and therefore in need of treatment. Likewise a roentgenogram taken several years previously and interpreted as normal has the same significance except that no inference can be drawn as to the time of infection. Lacking such help the physician must rely on his current findings. An adolescent or young adult patient presenting a lesion without definite evidence of fibrosis and calcification usually should have the benefit of treatment for at this age such lesions are almost always of recent origin and active. Furthermore this age carries with it a predisposition to rapidly progressive disease. For the same reason young people with apparently fibrotic and calcified pulmonary lesions should be studied closely since these older foci usually harbor infection which sometimes becomes active at this time of life or later and may require treatment for its control.

Older patients who appear healthy and whose lesions are judged to be densely fibrotic and calcified do not require treatment but only a roentgenographic examina-

quence in numerous cases was chronic pleural infection sometimes with a bronchopleural fistula and an incarceration of the lung in an enveloping fibrous membrane which more or less interfered with reexpansion at the termination of treatment. Because of its advantages modern treatment with chemotherapy has almost completely displaced pneumothorax therapy.

The choice of chemotherapy is determined chiefly by the known properties of the drugs (see p 257). Among the most generally employed regimens are isoniazid and PAS and streptomycin and PAS. In very acute and severe cases it may be reasonable at the start of treatment to administer the three drugs concomitantly at least until the infection has come under good control. Or it may be wise to administer for a time relatively large doses of isoniazid with the usual doses of PAS or streptomycin. Later it may be deemed better to reduce the dosage to the levels and intervals which help to avoid toxic effects and the early development of drug resistance. Once the lesions have reached a point of stability and promising healing an effective regimen of chemotherapy should be continued arbitrarily for another year or more in the moderately or far advanced cases. In the "minimal" case approximately six months may be sufficient. In the advanced bilateral cavity case in which full recovery cannot be expected chemotherapy should be continued indefinitely and different regimens may follow one another as bacterial resistance develops to the first defense drugs. In this way symptoms may be somewhat ameliorated and life prolonged.

The hospital or the home may be a suitable place for treatment depending on the exigencies of the case. It is significant that in many tuberculosis sanatoriums the number of patients treated today are no fewer than the number treated ten years ago but the average length of residence is materially shorter. Most patients with overtly active disease profit by hospital treatment during the early weeks or months. Toxic effects of poorly tolerated drugs become manifest usually within the first month or two of chemotherapy during this time close observation may be necessary to detect the early signs of harm and to make indicated changes in the regimen. Also in the hospital it is usually more feasible to conduct the frequent examinations which in the early period measure the quality and degree of response to treatment. If this

is not satisfactory and surgery later is probably indicated proper preparation can be made for it. Another reason for hospitalization may be the removal of the patient from the home until he is no longer likely to infect the other members of his family.

After the control of the disease has been reliably achieved and the prospect of firm healing seems assured the patient may be sent back home to continue treatment there. This presupposes of course that the conditions there are hygienic and reasonably conducive to his recovery and that the family is understanding and cooperative. There are a good many patients who are homeless or customarily live alone and who need to receive most of their treatment in hospitals. There are also patients with advanced chronic disease who unless they are affluent and otherwise exceptionally favored need some kind of permanent shelter preferably in a good institution where perhaps they may be given some light employment.

Many recovering patients benefit from the intelligent assistance which they may receive from friends, physicians and social agencies as they return to their social group, regain their self confidence and resume some gainful occupation. A necessity during treatment is the education of the patient on the nature of his disease and the modifications in his routine of living which it may impose immediately and in the future. This is done best by the physician who has had considerable experience but it may be learned readily also by the inexperienced if he is seriously interested.

**Treatment of Special Symptoms** Cough and expectoration if traceable usually to excavating lesions of the lungs and sometimes also to tuberculous laryngitis and bronchitis are best controlled by rest treatment and chemotherapy. The patient is instructed to suppress coughing if possible and to expectorate by gentle clearing of the throat. However it may be necessary to give sedatives such as codeine sulfate 0.03 gm at intervals of three or four hours or longer so that the patient may get sufficient rest. Sometimes this may be supplemented with a hypnotic at night. For the distressing cough of patients who have considerable bronchitis steam inhalations perhaps with the addition of some medication like creosote or tincture of benzoin may be alleviative.

**Hemoptysis** consisting only of slight streaks or spots of blood in the sputum requires no special additional treatment.

symptoms respond satisfactorily but in the mild and subacute forms this may occur within several weeks. As treatment continues the maximal effect to be expected next is the disappearance of cough and expectoration and of other symptoms then the patient is usually gaining weight and feeling well. During subsequent months the important criteria are the disappearance of tubercle bacilli from the sputum and gastric contents and evidences by physical and roentgenographic examination of progressive fibrosis with the closure of cavities. Chemotherapy is continued throughout but there is no absolute criterion of the degree and duration of rest to be prescribed in these later months. Some patients do well without a continuation of extra hours of bed rest beyond a good night's sleep perhaps with a short afternoon nap while others become easily fatigued these immediate sensations are significant. A further important condition is that which best favors progressive and firm fibrosis of the lesions the surest safeguard against a relapse—early or after some years of inactive infection. Unless compromises are forced by the urgency of returning to full-time work or by other circumstances it is wise to give these recovering patients the benefit of the added insurance which is provided by a prescribed routine of rest and activity for six months or a year after the point of complete freedom from symptoms absence of tubercle bacilli from sputum and gastric contents and favorable anatomical healing and stability of lesions has been reached in some this activity may include light part-time work.

Throughout the course the standard guides are obtained by a systematic observation of the patient's symptoms a record of his temperature pulse and body weight and of the amount and character of the sputum. Physical examination may reveal significant changes in the lungs particularly a diminution of rales but periodic roentgenograms are required to demonstrate the resolution of exudate the change in the size of cavities and the later delimitation by fibrosis. Early the roentgenograms should be taken every week or two then after the stabilization of lesions at intervals of a month or more. Counts of blood cells are made at the start but need not be repeated frequently unless there is an abnormality. Estimations of the erythrocyte sedimentation rate and of the serum proteins may be of value especially during the subclinical healing phases of the disease. An important necessity is the peri-

odic microscopic examination and culturing of the sputum for tubercle bacilli and if it is negative the culturing of gastric contents. Often a positive culture is the only demonstrable evidence of an unhealed lesion. In such cases the cultural determination of the susceptibility of the bacilli to various drugs may be indicated.

The foregoing information is related mainly to those patients with limited disease who under treatment go on steadily to improvement and eventual firm healing. But there are many advanced and complicated cases in which the treatment mentioned does not accomplish these ends. Usually because of the extent of destruction of tissue an impasse is reached where symptoms are more or less controlled but healing of the lesions does not occur to a comparable degree. Large caseous residuals and cavitory defects persist which are a constant threat of later relapse. If not too extensive these are best eliminated by surgical resection. Segments of lobes entire lobes or the whole lung may be removed depending on the degree of involvement. The operation involves the risk of complications including pleural infection and bronchopleural fistula but this is minimized by the proper choice of cases and timing of the surgery. It is advisable to delay the operation until severe symptoms have subsided and the pulmonary lesions have been brought under good control but not until the tubercle bacilli have become resistant to available drugs. If as a result of the resection a considerable unfilled pleural space remains it is often necessary at a subsequent operation to obliterate this by thoracoplasty—removing sections of a few or many ribs. This operation is sometimes chosen in lieu of resection especially if the disease is too extensive to be removed but a chronic apical cavity may be expected to heal when its walls are allowed to collapse and come into contact. Other measures to produce partial reduction of the volume of the lung include paralysis of the hemidiaphragm by crushing the phrenic nerve in the neck and artificial pneumoperitoneum but the value of these is usually questionable and limited. Artificial pneumothorax was widely practiced usually to collapse one diseased lung for many years prior to the advent of chemotherapy. The procedure continued in the given case by refills of air into the pleura for many months or several years had many excellent results but was attended by great risk of tuberculous pleural effusion empyema and fibrosis. The conse-

quence in numerous cases was chronic pleural infection sometimes with a bronchopleural fistula and an incarceration of the lung in an enveloping fibrous membrane which more or less interfered with re-expansion at the termination of treatment. Because of its advantages modern treatment with chemotherapy has almost completely displaced pneumothorax therapy.

The choice of chemotherapy is determined chiefly by the known properties of the drugs (see p. 257). Among the most generally employed regimens are isoniazid and PAS and streptomycin and PAS. In very acute and severe cases it may be reasonable at the start of treatment to administer the three drugs concomitantly at least until the infection has come under good control. Or it may be wise to administer for a time relatively large doses of isoniazid with the usual doses of PAS or streptomycin. Later it may be deemed better to reduce the dosage to the levels and intervals which help to avoid toxic effects and the early development of drug resistance. Once the lesions have reached a point of stability and promising healing, an effective regimen of chemotherapy should be continued arbitrarily for another year or more in the moderately or far advanced cases. In the "minimal case" approximately six months may be sufficient. In the advanced bilateral cavitary case in which full recovery cannot be expected chemotherapy should be continued indefinitely and different regimens may follow one another as bacterial resistance develops to the first defense drugs. In this way symptoms may be somewhat ameliorated and life prolonged.

The hospital or the home may be a suitable place for treatment depending on the exigencies of the case. It is significant that in many tuberculosis sanatoriums the number of patients treated today are no fewer than the number treated ten years ago but the average length of residence is materially shorter. Most patients with overtly active disease profit by hospital treatment during the early weeks or months. A necessity during treatment is the education of the patient on the nature of his disease and the modifications in his routine of living which it may impose immediately and in the future. This is done best by the physician who has had considerable experience but it may be learned readily also by the inexperienced if he is seriously interested.

**Treatment of Special Symptoms.** Cough and expectoration if traceable usually to excavating lesions of the lungs and sometimes also to tuberculous laryngitis and bronchitis are best controlled by rest, treatment and chemotherapy. The patient is instructed to suppress coughing if possible and to expectorate by gentle clearing of the throat. However it may be necessary to give sedatives such as codeine sulfate 0.03 gm. at intervals of three or four hours or longer so that the patient may get sufficient rest. Sometimes this may be supplemented with a hypnotic at night. For the distressing cough of patients who have considerable bronchitis steam inhalations perhaps with the addition of some medication like creosote or tincture of benzoin may be alleviative.

**Hemoptysis** consisting only of slight streaks or spots of blood in the sputum requires no special additional treatment.

Treatment of significant hemoptyses is designed to arrest the bleeding and to prevent a dissemination of the infection in the lungs by aspiration of contaminated blood. The patient should be in bed and in order to restore calm and quiet may be reassured justifiably that the bleeding will subside. Violent coughing favors aspiration of the blood into healthy alveoli. If the patient is unable sufficiently to restrain the impulse, codeine sulfate 0.03 to 0.06 gm. may be given hypodermically. Morphine is seldom indicated and then only in small doses 0.008 to 0.01 gm. Too much sedation depresses the reflexes unduly and may permit the retention of clots in the bronchi, which is undesirable. For a day or two after the initial hemoptysis dark clots may be expelled or fresh bleeding may occur usually in diminishing amount. If the hemorrhages are large or frequently repeated, especially in cases in which the disease is predominantly unilateral, artificial pneumothorax may relax the lung and with it the bleeding vessel; this procedure as a rule is effective. Usually, however, pneumothorax is postponed for a few days or longer until accumulated blood has been cleared from the air passages, since this lessens the possibility of acute pneumonic reactions and serofibrinous pleurisy after the pneumothorax. If pneumothorax fails, other forms of collapse therapy may be considered in emergencies, occasionally thoracoplasty or resection of a cavity-bearing lobe is indicated without delay. However, most hemoptyses subside after the loss of a small or moderate amount of blood and treatment may then be continued according to the usual indications. During and for a few days after the hemoptysis the patient is given a soft or light diet according to his desires and it is not necessary usually to restrict this to fluids. The patient is encouraged to lie on the affected side but during the waking hours he should change his position from time to time, since this aids in expelling clots of blood. Hemoptysis is relatively very infrequent while a patient is receiving chemotherapy; if bleeding does occur, new areas of pneumonic infiltration may follow but the continued therapy usually prevents much caseation and rapid resolution is often observed.

Dyspnea of sudden onset usually is due to acute pneumothorax or pleurisy and is treated accordingly. In advanced fibroid cases the symptom may become aggravated during attacks of acute bronchitis or bronchopneumonia when oxygen therapy is indicated for relief.

Pain in the chest is traceable most often to pleuritic involvement; strapping with adhesive plaster may give relief.

Night sweats are relieved usually by rest in bed and proper nursing. Drugs such as atropine or agaricin have little effect. The patient should not be covered too heavily with bed clothes and the room should be airy and cool. Alcohol rubs or baths before retiring are helpful. After the sweat the clothing should be changed and the patient should be given an alcohol rub.

Anemia is treated by a good general diet and by appropriate chemotherapy and vitamins as indicated. Sometimes the most effective measure is the proper treatment of a complicating intestinal tuberculosis.

Rehabilitation, which consists in developing plans for good living and suitable work after recovery may be instituted as soon as conditions warrant. In many instances good morale and cooperation in treatment are promoted by encouraging the patient to see the goal of recovery ahead and by educating him to plan according to probable future opportunities and limitations. Early in his treatment his aptitudes may be estimated by approved testing; he may receive expert advice on vocations for which he is suited and when able begin study and training as he chooses. In many hospitals and sanatoriums facilities and trained personnel are now available to render such services to patients.

**Maintaining Arrest and Avoiding Relapse**  
In many advanced cases of tuberculosis the physician must recognize the impossibility of complete arrest of the disease and strive only to alleviate symptoms. But when there is a prospect of returning the patient to useful life, it is important to estimate when treatment has been sufficient to assure stability of the disease in the situations he is obliged to face later.

According to the standards of the National Tuberculosis Association, the disease is considered inactive when the lesions have remained apparently healed, tubercle bacilli have not been demonstrable and the patient has been symptom free for at least six months. As the lesions still harbor viable tubercle bacilli and relapse is possible, the gains are to be maintained and consolidated during the next several years. Experience shows that if the patient goes through two years with continuing "arrest" the chance of relapse later is greatly minimized. During this time close and systematic medical observation and advice are important, as is the cooperation of the patient in following faithfully the prescribed

daily routine. In most successfully treated cases six months to a year of "arrest" should elapse before the patient returns to work. During the interval as far as practicable his daily schedule of activity should be increased gradually until it approximates that which he expects to continue at work. Patients who have followed light or sedentary occupations usually do best in returning to them particularly if the employer is willing to make some concessions pending complete rehabilitation. One half day's work may be safe at first to be gradually increased during the following months or years. Other patients often have to be educated for a new occupation since laborious work under unfavorable conditions is always to be interdicted.

Periodic medical supervision is indicated indefinitely after recovery. At first the patient should be seen once a month during this time he should be questioned about symptoms the sputum should be searched for tubercle bacilli and a roentgenogram should be made for comparison with those previously accumulated. Continued good general health, absence of tubercle bacilli and unchanging roentgenographic shadows (except perhaps for slight further contraction of the fibrotic lesions) permit as a rule continuation or expansion of the daily routine. After three or four months the interval between examinations may be gradually lengthened but for the first two or three years the patient should be observed in this way every three to six months and afterward at least once a year. The appearance of symptoms should always be the occasion for medical examination to determine the cause.

#### TUBERCULOSIS IN CHILDREN

In children the lesions of primary pulmonary infection have features which differ somewhat from the manifestations in adults. The primary parenchymal lesion is less likely in children to go on immediately to progressive excavation but there is a pronounced tendency to gross involvement of the bronchopulmonary tracheobronchial and other mediastinal lymph nodes. Consequently physical examination though it should not be omitted does not reveal the true nature of the lesion as well as it usually does in adults. Roentgenographic examination is a necessity. In children more than in adults enlarged lymph nodes may compress the bronchi in the root of the lung which in turn may lead to nonspecific changes distally in the parenchyma. Extension of the infection from the nodes may

involve adjacent structures eventually resulting in damage such as ulceration and stenosis of the bronchus and traction diverticula of the esophagus. On the other hand inflammation of the nodes often subsides and their size diminishes strikingly leaving relatively small calcific residues (Fig 31).

Because of the frequent hemic dissemination of tubercle bacilli there is a relatively high incidence of meningitis and generalized miliary disease among infants. This according to Wallgren is most apt to occur within the first three months after the primary infection. Barring such catastrophes lesions may evolve within a few months or even after a period of years at local sites such as the bones and joints and the genitourinary tract. Also although fatalities are relatively rare between the ages of two and ten or twelve latent pulmonary lesions remaining from the primary infection acquired in childhood have a definite tendency to flare up in adolescence and early adult life. This hazard increases somewhat in proportion to the greater extent and caseous character of the latent lesions.

**Treatment.** The local primary lesions in the parenchyma and lymph nodes of children tend to run a benign course and to undergo considerable resolution. On this

FIG 31 Apparently calcified tuberculous lesions in the right lung and bronchopulmonary lymph nodes (primary complex).

account it is difficult at times to estimate in individuals the additional benefit derived from chemotherapy. Experience with large groups of children however has yielded evidence of the powerfully favorable effects of the drugs. A number of clinicians among whom Edith M. Lincoln and her associates at Bellevue Hospital have had a long and well documented experience have reported a lowering of the fatality of manifestly active disease by approximately 90 per cent. As in adults widely destructive cavitary disease of the lung may be brought under sufficient control to permit surgical resection. Bronchial (endo bronchial) tuberculosis due to direct extension from contiguous caseous lymph nodes a relatively common problem in children is not strikingly influenced by chemotherapy (Lincoln *et al.* 1956) probably because of the persistence of infection in the underlying focus. By contrast in adults in whom bronchial lesions are usually more superficially situated in the mucosa and caused by infection from draining parenchymal cavities the response to such treatment is generally very good. A regimen which contains isoniazid has been shown to reduce the risk of meningitis in infected children and this is strong evidence that such chemotherapy suppresses the infection in local lesions and also arrests the destruction of tissue which in some cases causes a break in the pulmonary vein and allows the escape of bacilli into the blood stream.

It has become a common practice to treat infected children under two years of age with chemotherapy chiefly to avoid these early complications (Bentley 1956) and some advocate this up to the age of four. It remains to be seen however whether such practice will reduce the risk of a flare up of latent lesions in adolescence.

#### TUBERCULOSIS OF THE LARYNX, TRACHEA AND BRONCHI

*Tuberculous laryngitis* is one of the common complications of chronic pulmonary tuberculosis. The lesions may be chronic and localized or acute exudative and diffuse. The lesion usually appears first at the level of the vocal cords or the arytenoids in the posterior part of the larynx. There may be a diffuse swelling or tubercle formation of the mucosa in the interarytenoid space, at the posterior end of one or both vocal cords or in the region of one or both arytenoid cartilages. The inflammation may become almost completely resolved or it may progress with caseation and ulceration. The irregular ragged shallow ulcers are

found usually in the locations mentioned. Later granulations may develop which have a serrated granular or tubercular form. If extensive fibrosis may cause slight stenosis of the larynx. The early symptoms are huskiness and hoarseness of the voice, dryness and slight soreness of the larynx. This may be noticed only on awaking or after talking but usually continues beyond the time expected for simple catarrhal laryngitis. Laryngoscopic examination then may show the typical changes. Later if the lesions progress hoarseness becomes chronic and continuous and the dryness and irritation may cause moderate or severe coughing. Pain is not usually a pronounced symptom unless deep invasion of the laryngeal cartilages occurs. One of these the epiglottis may become greatly enlarged swollen red and finally deeply ulcerated. Such extensive disease results in dysphonia, severe dysphagia and salivation and the patient's nutrition may be seriously impaired. In treatment an important principle is vocal rest, the patient being instructed to abstain from using the vocal cords. In these cases specific chemotherapy is indicated not only for the laryngeal disease but also for the pulmonary tuberculosis, the regimens being the same. The response of the laryngitis is usually very satisfactory, sometimes dramatically so. Painful symptoms often disappear rapidly.

The bronchi leading from a tuberculous pulmonary cavity usually are invaded and in some cases lesions in the larger bronchi or trachea assume important clinical significance. Shallow lenticular ulcers of the mucosa are not uncommon and more pronounced lesions develop occasionally in patients especially women with longstanding pulmonary disease. The bronchial wall may be attacked also by lesions in contiguous lymph nodes. The bronchial lesions consist of ulcers which are superficial or penetrate to or through the cartilage or of granulomatous and fibrous formations which may partially occlude the lumen. Healing in the early stages leaves little or no scar but more advanced lesions may be followed by extensive organization of the bronchial and peribronchial tissues with contraction and cicatricial stenosis. The affected bronchus may fail in its function as a drainage tube and in this event the related segment of the lung becomes involved with secondary pyogenic infection resulting in bronchopneumonia which may be necrotizing and associated with bronchiectasis. The diagnosis depends on eliciting the history of symptoms such as persistent

severe coughing and wheezing and the auscultation of rhonchi confined mostly to one side of the chest or to one lobe. Foulness of the sputum is suggestive of complicating anaerobic infection which often involves the parenchyma distal to the bronchial obstruction. Roentgenographic evidence of obstructive emphysema or cavities which appear distended and partly filled with fluid or of diffuse pneumonia is suggestive. Bronchoscopy may disclose the lesions. Chemotherapy for the pulmonary tuberculosis is often quite effective in part because of the reduction of purulent discharge passing over the bronchial surfaces. At the same time the subsidence of bronchial edema allows better drainage of pulmonary cavities thus favoring their healing. However if the bronchus becomes narrowly constricted during its fibrous repair lobectomy or even pneumonectomy may be necessary to prevent or remove the chronic destructive secondarily infected parenchymal disease which ensues almost inevitably.

#### TUBERCULOSIS OF THE ALIMENTARY TRACT

*Tuberculosis of the mouth* appears most often as ulceration of the tongue which becomes infected as a rule by extension from a laryngeal lesion or through an abrasion caused by biting or other trauma from the teeth. The lesion is situated most often on the margin but may involve the dorsum especially at the base. The ulcer at first is superficial but progressive infiltration and caseation often follow with extensive destruction of the muscle. The chronic ulcers are often fissured and yellow caseous or red granulating tubercles may be found in their depths. The indurated base is usually palpable. The ulcer is usually single but others may appear. The diagnosis depends on the finding of such a lesion in a tuberculous patient and may be confirmed by demonstrating the organisms in curettings from the ulcer. Biopsy is to be avoided unless necessary. Specific chemotherapy may bring about partial or complete healing.

*Tuberculosis of the lip or gingiva* is found usually under similar circumstances the lesion appearing much the same as that of the tongue. An ulcer at the corner of the mouth may be fissure like and penetrate deeply.

*Tuberculosis of the salivary glands* is rare possibly because of the alkaline reaction of the tissue (Vivoli *et al.*)

*Tuberculosis of the pharynx* is found most often in association with lesions of

the *tonsil*. Infection of the latter may be due to surface contamination or to hemic dissemination from a distant focus. Upon examining 2000 pairs of tonsils removed surgically Long Seibert and Gonzales found that the incidence of tuberculous lesions depends roughly on the prevalence of tuberculosis in the community. It was 6.5 per cent in specimens from American Indians, 2.5 and 0.25 per cent in those from Puerto Ricans and Philadelphians respectively. The lesions are usually deep and focal. In cases recognized clinically the tonsil is slightly or moderately enlarged and may show yellow or whitish caseous areas beneath the shiny mucosa. Later these break down leaving grayish yellow ragged ulcers. One or both tonsils may be involved. When the pharynx becomes infected secondarily the fauces, soft palate and uvula become thickly seeded with granular milium tubercles some of which have a minute yellowish center. These coalesce break down and form fissured ulcers and the tissues may be slowly destroyed. The pain is severe, salivation profuse and dysphagia marked. Such extensive disease is usually fatal unless it can be controlled early by specific treatment.

*Tuberculosis of the esophagus* is relatively rare. The upper end may be involved by direct extension from severe tuberculosis of the larynx. Tuberculous lymph nodes of the mediastinum after caseation may perforate the esophagus discharging their contents or the perinodal inflammation may involve the esophagus without perforation. In either event the cicatricial contraction may produce diverticula of the esophagus.

*Tuberculosis of the stomach* is reported in a few cases of pulmonary disease at autopsy (up to 1 per cent). The lesions usually extend to the stomach from a contiguous adherent lymph node but they may result from surface contamination of the mucosa by swallowed discharges from the lungs. The gastric wall may be infiltrated or there may be an ulcer usually near the pylorus which grossly resembles carcinoma.

The *intestine* is most frequently involved the commonest site being the lower ileum and cecum. The mechanism of infection is principally surface contamination with swallowed tubercle bacilli in patients with pulmonary tuberculosis (up to 70 per cent at autopsy). Much less often infection may be caused by primary invasion (e.g. contaminated milk) hemic dissemination or extension from tuberculous peri-

tonitis Infiltration of the intestinal mucosa and lymphoid tissue usually is followed soon by superficial ulceration the ulcers may extend rapidly or become localized and chronic with an organizing granulating base and overlying fibrinous or fibrous peritonitis Sometimes as in the cecum the proliferative granulomatous changes become protracted leading to great thickening of the wall fibrous peritonitis and narrowing of the intestinal lumen the whole forming a tumorous mass Acutely progressive ulceration may involve several feet of the intestinal mucosa enclosing small islands of intact tissue Perforation of the wall by the ulcer is infrequent Small ulcers may heal and the mucosa apparently regenerate

The initial symptoms are indefinite and considerable ulceration may be found in patients who have never had abdominal complaints At first there is slight to moderate loss of weight vague indigestion loss of appetite irritability and secondary anemia Local symptoms may appear early or late as a change in the usual rhythm of the stools A short attack of mild diarrhea may be followed by constipation and after an apparently normal interval this may recur After many weeks or months diarrhea may become frequent and finally the patient will have ten to twelve evacuations during the day and night the diarrhea being watery and foul seldom bloody The diarrheal attacks are associated often with colicky pains in the lower half of the abdomen aggravated perhaps by taking certain foods such as raw fruit The patient may become emaciated Physical examination usually reveals no palpable masses and frequently no tenderness although the patient may complain of a little soreness on deep palpation especially in the right lower quadrant In certain mild chronic cases the recurrent pain simulates simple chronic appendicitis in fact the appendix may be involved in the tuberculous process Some times this is not suspected until the lesions are discovered on routine histological examination of the resected appendix In cases of tuberculous enterocolitis roentgenographic examination after a barium meal or enema may reveal spasticity filling defects and hypermotility of the lower ileum cecum and ascending colon Treatment consists first in proper general management and prescribed rest since these patients almost always have chronic pulmonary tuberculosis The diet should be bland raw fruits fruit juices and fat may have to be reduced or eliminated temporarily

and vitamins given parenterally Medication to relieve pain and lessen the intestinal spasm may be indicated in the form of powdered opium or paregonic bismuth subnitrate or bismuth subgallate by mouth or calcium gluconate intravenously Specific chemotherapy is highly effective

*Tuberculous ischio-rectal abscess or perianal abscess and fistula* are due usually to infection in a similar way and start with a localized painful perianal swelling which becomes acutely tender within a few days or several weeks If not incised this may perforate the skin to the exterior less often the wall of the rectum with the discharge of nonodorous pus in which tubercle bacilli may be demonstrated The resulting fistula is apt to be chronic and later to require surgical treatment However if the original abscess was rather superficial and drains freely it may heal satisfactorily with chemotherapy administered in the usual way Local applications of one or more of the drugs have been tried but this seldom seems to be necessary except following surgical resection of the fistula

#### GENERALIZED FORMS OF TUBERCULOSIS

##### ACUTE GENERALIZED MILIARY TUBERCULOSIS

The disease occurs most frequently in young children or infants and occasionally in adult life especially in men over sixty years of age The patient may have been in perfectly good health previously or may have had some clinical or other demonstrable evidence of tuberculosis such as roentgenographic signs of mediastinal lymph node involvement (Fig 31) The onset may be abrupt with chilliness prostration aching in the muscles headache and drowsiness or gradual with malaise weakness and fatigue for a period of a few days or a week before the patient becomes prostrated The temperature may rise at once to 103° or 104° F in the afternoons or attain this level gradually during a week or so Night sweats may be profuse the soft tissues waste rapidly and the patient is overcome by weakness Localizing symptoms depend on the predominant distribution of miliary tubercles Dyspnea and cyanosis may become pronounced because of the extensive and rapid invasion of the lungs but there is usually no cough or only a slight hacking In other cases peritoneal symptoms such as pain distention and constipation may predominate Effusions may accumulate in the serous cavities with the well known clinical manifestations of their presence if they are profuse

Physical examination initially shows only the general effects of the toxicity. After a week or more fleeting rales may be heard in the lungs later numerous and persisting fluid may be demonstrated occasionally in the pleura or peritoneum less often in the pericardium. The spleen becomes palpable in only a minority of the cases. Tubercles are seen somewhat less frequently in the choroid of adults than of children. The roentgenogram of the chest is indeterminate at first but usually shows characteristic stippling of the pulmonary fields within several weeks. The leukocyte count usually remains within normal limits but occasionally becomes moderately elevated seldom above 20 000 per cu mm. Leukemoid reactions and aplastic anemia due presumably to invasion of the bone marrow are rare complications.

A biopsy of the bone marrow may show tuberculous changes and sometimes tubercle bacilli may be grown in cultures seeded with the aspirated marrow. Occasionally the organisms are also grown from the blood but they seem to disappear soon after dissemination from the focus of origin ceases. The situation may be aggravated by supervening meningitis which may develop early or late in the course. In DeBres 170 cases of military disease in children meningitis occurred in 88 per cent of the acute forms and in about 50 per cent of the subacute.

Treatment with combinations of specific drugs should be started as soon as the diagnosis is made. Initially streptomycin (2.0 gm daily) and isoniazid (400 to 600 mg daily) are administered to adult patients. Many prefer to add para-aminosalicylic acid (10 to 15 gm daily). In early cases a symptomatic response with gradual lowering of the temperature to normal levels within two to eight weeks is the rule. At the same time a gradual fading of the military shadows from the roentgenogram of the lungs is observed. As the temperature becomes normal the dose of streptomycin is reduced to 1.0 gm daily and that of isoniazid to 200 to 300 mg daily chiefly to avoid the toxic effects of the drugs. This regimen is continued for two or three months longer after which streptomycin is further reduced to 1.0 gm three times a week (every other day). This regimen then is maintained for a year or more depending on the original severity of the case.

The importance of isoniazid in the regimen of therapy is demonstrated by the experience of the Veterans Administration Army and Navy hospitals reported by J. H.

Williams Jr (1957). Compared with a five year survival rate of 52 per cent after treatment with streptomycin alone 57 per cent with streptomycin sulfone and 80 per cent with streptomycin PAS the introduction of an isoniazid streptomycin regimen in 87 cases is credited with a two-year survival rate of 95 per cent. None of these developed meningitis during a year or more of observation after the start of treatment whereas the incidence of this complication among 100 patients treated with streptomycin alone was 40 per cent and among those treated with streptomycin PAS it was 22 per cent.

### SUBACUTE FORMS

The subacute forms are likewise observed most often in the early ages but occasionally also in adults particularly Negroes. Tubercle bacilli enter the lymph or blood stream perhaps at recurring intervals from a caseous focus. The number of lesions established in various organs is only moderate and since the patient does not die soon time is sufficient to permit further local development with necrosis or partial healing. Many bacilli are picked up by the lymphatics and come to rest in various regional lymph nodes. The lungs are frequently involved the lesions being particularly prominent in the upper parts. The spleen, kidneys, liver and serous membranes often participate.

The variety of clinical manifestations is great but some are fairly constant. The patient may have obscure fever which has persisted for days or weeks without other obvious symptoms except loss of weight, malaise and fatigue. In time peripheral lymphadenopathies may become apparent as in the auricular, cervical, axillary, epitrochlear and inguinal regions. A roentgenogram of the chest may show only widening of the upper mediastinum from the lymphatic lesions. The spleen may become palpable within a few weeks or months. Other patients with similar fever reveal evidence only of an effusion in the pleura, peritoneum or perhaps in several or all of the serous cavities. Still others may be found to have genitourinary tuberculosis and occasionally pyonecrotic lesions of the skin give the first clue to the identity of the fever. Multiple lesions in the bones and joints and in the eye may be associated some may become ulcerous or fistulous.

The natural course unless interrupted by chemotherapy is almost always progressively unfavorable. Most patients die in

three to six months some with an acute miliary dissemination at the end. A few survive longer when the disease may evolve in one or more local sites usually the lungs progressive cavitory lesions then may appear.

Treatment is the same as that for the acute form. Since the early course of the subacute forms is relatively mild and the diagnosis often uncertain necrosis in many of the disseminated lesions may have occurred before treatment is started. Consequently the possibility of a late relapse may be greater than it is in the promptly treated acute case.

#### LATENT AND CHRONIC FORMS

It is not uncommon at autopsy to find tubercles originating obviously in hemic dissemination of the infection perhaps many years before distributed in such structures as the spleen, liver, kidneys, lungs and lymph nodes. These may be small even microscopic gray tubercles isolated in fibrous capsules. Others are represented by encapsulated round calcified nodules. Although these foci may still harbor living organisms and lead to local exacerbations they usually remain latent during the life of the person in whom they may be demonstrated by roentgenographic examination. Lesions of disseminated fungal infections especially histoplasmosis often have a similar form and distribution and are to be strongly suspected in endemic areas. Undoubtedly in the past many of these cases were wrongly interpreted as tuberculosis. It may require the demonstration of the causative organism in the stained tissue to make the distinction.

Among patients who recover from acute or subacute generalized tuberculosis it is to be expected that some may have local recurrences at sites where the lesions may not have healed sufficiently. The lungs then may be the site of numerous scattered fibroid lesions which cause some functional difficulty and among them may be some small caseous lesions which progress break down and become the sources of bronchial dissemination. It has become apparent however that scattered pulmonary lesions of a chronic nature are almost always the result not of blood borne infection but of bronchial dissemination from a sloughing local focus. Spain has produced pathological evidence that tubercle bacilli in the blood stream are not completely filtered out in the lungs when pulmonary lesions of this origin were identified he always found

lesions elsewhere chiefly in the abdominal organs (see Pathogenesis p 250).

#### TUBERCULOSIS OF THE SEROUS MEMBRANES

Any of the serous membranes may be come infected usually singly but some times in combination. The pleura is most commonly involved secondly the peritoneum less often the pericardium. The way of infection is by direct extension from some contiguous tuberculous lesion less often by the blood or lymph streams. The lesions appear as isolated tubercles or as fibrinous or serofibrinous inflammations. Fibrinous changes usually are rather limited while serofibrinous inflammations involve the whole membrane which is edematous and red. The serous exudate may be absorbed and fibrinous deposits may be come partially or completely resolved. As a rule however some of the endothelial lining is destroyed granulations develop and eventually are transformed into fibrous tissue adjacent surfaces may be bound together by firm adhesions in which lymph and blood vessels may develop. In relatively few cases the effusion becomes purulent deep inflammation and granulomatous thickening of the serosa occur and this may undergo caseous degeneration. Subsequent organization and fibrosis leave behind permanent thickening and adhesions of the membranes with distortions and retractions of adjacent structures. The serous or purulent exudate may become loculated. After some years if this is absorbed incompletely or slowly free cholesterol accumulates in the fluid and the organizing walls of the pockets become infiltrated with calcium salts. Calcification of the pleura is seen occasionally calcifications of the pericardium less often calcification of the peritoneum rarely.

Treatment of tuberculosis of the serous membranes should take into consideration that the infection is not primary here but originates most often in a local underlying focus. Infrequently as a manifestation of hemic dissemination from a distant lesion it is treated as a part of the generalized disease. Usually however attention is given to searching for the contiguous focus if this is not already manifest common sites are mentioned below. The serositis may soon subside spontaneously or under treatment but this should be given until the underlying infection which obviously was active is assumed to be controlled. Even though streptomycin, isoniazid or

PAS administered in the usual way diffuses into serous and purulent effusions their absorption is apparently not hastened. Given within a few days of the onset of the effusion the acute general symptoms may be ameliorated and the accumulation of fluid may be limited.

#### TUBERCULOSIS OF THE PLEURA

The commonest form is fibrinous pleurisy and this usually overlies a pulmonary lesion. Serofibrinous pleurisy develops in approximately 10 per cent of all cases of pulmonary tuberculosis. It may also be a manifestation of generalized tuberculosis. It is discussed in detail in the Section on Diseases of the Pleura. By the addition of adequate chemotherapy to the treatment of patients with tuberculous pleural effusion but without visible parenchymal disease Emerson (1957) found the five year morbidity rate reduced to 4 per cent among 83 patients. This occurred in spite of the fact that there was no reduction in the duration of the effusion, the accelerated erythrocyte sedimentation rate or the duration of the pyrexia.

Tuberculous empyema is related usually to some peculiar situation such as pleural ulceration and rupture or artificial pneumothorax and is considered in this connection. The effusions complicating pneumothorax treatment are usually serous or serofibrinous but in some cases there is a large output of polymorphonuclear leukocytes which rapidly undergo degeneration giving the fluid at first a cloudy appearance and later a thick light yellow or greenish creamy consistency. Tubercle bacilli may be demonstrable easily microscopically and may appear in large clumps. A thick coating of fibrin and coagulated nucleoprotein is deposited on all the pleural surfaces. Unless the exudate is absorbed early or organizing pleurisy enveloping the collapsed lung may bind this down and prevent its re-expansion.

Pneumothorax in tuberculous cases is related either to the ulceration of a subpleural caseous focus or to the rupture of a subpleural bulla which has developed secondary to the fibrosis. For a detailed discussion of this entity the reader is referred to the section on Diseases of the Pleura.

Tuberculosis of the peritoneum may be the result of hemic infection or of extension from local lesions such as retroperitoneal lymph node involvement or salpingitis. Fibrinous inflammation in the visceral peritoneum at the site of intestinal ulcers is a

common finding. General involvement may be milky serofibrinous or plastic and adhesive. Serofibrinous peritonitis may have an acute or insidious onset with constitutional symptoms like those described for serofibrinous pleurisy. Abdominal pain and tenderness are usually slight or moderate occasionally very intense. Initially there may be some vomiting and diarrhea but later constipation is the rule. Abdominal distention may be great due to ascites and tympanites but in other cases the wall is spastic and scaphoid. As adhesions develop the exudate may become loculated in pockets and the omentum and intestine matted.

Exudative peritonitis is most common in children and young adults but may occur even in old people. It is observed more often in Negroes than in white persons and in females than in males. Occasionally it is a complication of cirrhosis of the liver. Under treatment which includes chemotherapy for a year to two years the prognosis for recovery is good. (It is also to be assumed that the treatment of generalized tuberculosis will abort or prevent peritonitis in many cases.) Mechanical symptoms may require evacuation of the fluid to avoid perforating the gut; this is done best by a small surgical incision. Laparotomy is unnecessary in most cases. In female patients tuberculosis of the fallopian tube may prolong the peritonitis and favor chronicity; in such cases salpingectomy may later be indicated.

Plastic adhesive peritonitis usually is a later development of fibrinous or serofibrinous inflammation. Fibrous contraction may produce narrowing of the lumen of the bowel, the coils of which may be bound together in large inseparable tangles. Between the hyperplastic and caseous lesions tuberculous exudate sometimes purulent may be pocketed. Abdominal examination may reveal irregular masses of involved omentum matted intestine, caseous deposits or enlarged lymph nodes. These may be numerous or confined to a single section such as the right lower quadrant surrounding the cecum. Aside from the manifestations of chronic toxicity, local symptoms may become distressing on account of the fixation and stenosis of the bowel. There may be constipation, obstipation or occasionally obstruction. Rarely the intestine is perforated and tuberculous pus may drain from the peritoneum into it.

Treatment is general and symptomatic unless the disease is localized and accessible, such as a hyperplastic process in and surrounding the cecum; this may be re-

sected surgically. Postoperative abdominal fistulas which may be fecal are not uncommon. In most cases especially those treated early the course of the disease is arrested or favorably influenced by chemotherapy. Kahrs reports the outcome of 169 cases treated in Norway between 1930 and 1948 (mostly without chemotherapy). He found the serous type to have the most favorable outlook (20 deaths in 73 cases after 2.5 to 20.5 years) while the fibrinopurulent and purulent types (9 cases) all ended fatally.

**Tuberculosis of the pericardium** may represent an extension from the pleura in which case the lesions are usually of a localized fibrinous hyperplastic or adhesive character giving rise to few or no symptoms. Serofibrinous pericarditis is caused by direct extension of the infection from adjacent caseous lymph nodes or less often by hemic infection. Among all cases of pericarditis tuberculosis is identified as the cause in approximately 7 to 11 per cent (Reeves Griffith and Wallace). Aside from the manifestations of toxicity symptoms and signs referable to tamponade of the heart may be found the embarrassment may be relieved by paracentesis. The effusion may continue reaccumulating and after three to six weeks loculation may occur because of the formation of fibrinous adhesions. Caseation is observed occasionally especially in Negroes and may extend into the myocardium. In the few cases of recovery the layers of the pericardium may adhere completely and in time the shrinkage may lead to chronic constrictive pericarditis with functional impairment. In this disabling situation the operation of pericardiectomy or cardiolysis may effect partial or complete relief in 60 per cent of the cases (Heuer and Stewart).

Treatment is basically the same as that for tuberculous pleurisy and should take into consideration associated disease in the lungs and elsewhere. Chemotherapy is indicated and usually should be continued for a year or more.

#### TUBERCULOSIS OF THE LYMPH NODES

Lymph nodes may be infected by tubercle bacilli entering the lymphatic stream from a lesion in the tributary region or arriving by way of the blood stream. Most often the lesions are limited to a single chain frequently the mediastinal system. However in generalized forms of tuberculosis multiple scattered lymphadenopathies are demonstrated commonly in the superficial and deep chains. The lesions may

appear as acute subacute or insidious inflammatory swelling of the nodes with gradual caseation and necrosis. Perinodal inflammation and agglutination with adjacent nodes may follow later liquefaction, rupture and sloughing of the contents through the overlying tissues particularly in superficial involvement. As the inflammation subsides calcification of the caseous residues may develop slowly during a period of years and the lesions may remain as permanently enlarged firm usually discrete nodes. Sometimes chronic fistulas usually superficial persist and may burrow widely causing extensive degeneration of the skin and subcutaneous tissues (scrofuloderma). Most often lymphadenitis is of a mild hyperplastic type with only a minimum of caseation. The lesions may be chronic or may subside and become reactivated repeatedly after long or short intervals of time without any evidence of liquefaction or sloughing. In the chronic systemic forms of tuberculosis the lymphatic system may harbor most of the lesions and account for the protracted ill health including exacerbations of low fever from time to time.

Specific chemotherapy for tuberculosis of lymph nodes is subject to the same general principles previously discussed and to an estimation of the prognosis. Often the disease is a mild self limited process and the important thing is to build up general resistance to avoid a recurrence. In acute cases specific therapy may help materially to halt the inflammation and promote resolution but a lasting effect on the caseous components is not to be expected. These require a long time for natural healing may liquefy in spite of specific therapy and when accessible may eventually require surgical treatment.

**Mediastinal and bronchopulmonary lymph node tuberculosis** is observed most often in young children following the primary infection. Constitutional symptoms may be mild or entirely lacking. Massive lesions may produce pressure giving a variety of symptoms such as stridulous cough simulating whooping cough constant or intermittent wheezing respiration sometimes simulating asthma less commonly stridor, dyspnea and cyanosis. Localized pressures on the bronchi may irritate and compress the tube resulting in collapse of the lobe or the lung or the development of nonspecific necrotizing bronchopneumonia and possibly bronchiectasis. Perforation of the nodes through the trachea more often the bronchi occurs most often during infancy.

and early childhood and very seldom during adult life the tubercle bacilli thus discharged may then be aspirated into the lung causing tuberculous bronchopneumonia. Calcified nodes similarly may ulcerate through the bronchi (broncholithiasis). Physical examination usually is not helpful unless the mass is very large then it may be suspected by dullness and altered breath and voice sounds extending beyond the spine or sternum on one or both sides. The roentgenogram reveals the lesions unless they are small and concealed by other structures the shadows include bulbous enlargements of the hilum widening of the mediastinal density and the round and oblong homogenous or granular opacities of calcification. With few exceptions the tuberculin test is positive and often there are typical lesions also in the lungs or else where. Occasionally physical signs and symptoms of bronchial stenosis or tracheal and venous obstruction may be elicited. Diseased nodes which are not greatly enlarged or extensively caseated have a tendency to subside and heal without special treatment and the finding of calcified residues in later years is the common evidence of this. The need for and duration of chemotherapy and supportive treatment are based therefore on the recognition of certain risks which are somewhat peculiar to primary tuberculosis. These include recently acquired active and extensive lesions disease in the parenchyma of the lungs or elsewhere and the age of the patient. In infants for instance chemotherapy is intended to avoid the development of systemic disease as well as to promote the healing of the primary sources. Surgical removal of massive diseased nodes has been accomplished but is seldom undertaken.

**Cervical lymphadenitis** is a common form but in the United States has become much less prevalent since the early nineteen hundreds. The disease which was known in earlier times as scrofula or King's evil has been reduced through the elimination of tubercle bacilli from milk and the prevention of infection in childhood. The lesions may be confined to one or several nodes or may encircle the neck anteriorly from ear to ear. The upper deep cervical nodes are most frequently affected as a rule the lesions are more pronounced on one side. Infrequently the acute swelling is so marked as to impede the motion of the neck and to displace the trachea. If the onset is insidious the lumps may be discovered purely accidentally. Tenderness is slight or moderate unless the overlying tissues be

come involved. The skin usually appears healthy but may become red tender and gradually thinned out until perforation occurs. A thick or nummular purulent discharge follows and drainage may continue for a long time. Neglect of the condition may result in fistulas in various parts of the neck and in the upper thorax. Treatment during the acute stages includes the use of chemotherapy. This usually controls the active inflammation and dries discharging sinuses. Afterwards surgical excision of chronically enlarged and necrotic nodes may be indicated if these are deemed likely to break down again. Chemotherapy then is continued until healing is well established. In cases of fluctuant nodes and draining sinuses treatment by wide incision irrigation and packing with streptococcal enzyme (streptokinase streptodornase) has been reported by Anastasiades *et al* (1957) to produce satisfactory results in a majority of twenty nine children.

**Abdominal lymphadenitis** may be part of a generalized infection or may result from lesions in the intestine peritoneum or other adjacent organs. Usually there are no specifically localizing symptoms but when the involvement is moderate or extensive vague abdominal pain constipation and indigestion may be complaints. Sometimes the condition simulates chronic appendicitis. Advanced wasting disease in infants and young children is known as *tuberculosis mesenterica*. Unless the lesions originally were extensive or part of generalized tuberculosis the tendency to heal is striking. In chronic cases the infection may spread through adherent lymph nodes into the stomach duodenum pancreas or liver. Adjacent iliac veins may become thrombosed rarely a node perforates and discharges into the aorta.

#### TUBERCULOSIS OF THE URINARY TRACT

The kidney is the most frequent site of tuberculosis of the urinary tract the infection usually being blood borne. In males the infection sometimes extends to the urinary tract from the genitals. The disease is much more prevalent in adults than in children and is observed two to four times as frequently in males as in females. The finding of microscopic tubercles in the kidneys is common at autopsy but gross lesions are detected in 10 per cent or less of all cases of chronic pulmonary tuberculosis. The disease often occurs in patients who have never suffered from pulmonary lesions the presumption being that the infection was carried from a primary focus which subse-

quently healed Renal lesions may be latent for a long time before causing clinical symptoms The early lesion is usually in or near the glomerulus and bacilli may pass from this through the tubules to the papilla Caseation and ulceration may be limited or extensive resulting in the formation of small fistulas and the discharge of bacilli into the renal pelvis and ureter These more resistant structures also may be invaded Often the kidney becomes more or less excavated Occasionally the caseous lesions may be encapsulated or the ureters become sealed off then calcareous changes may develop The bladder may be infected with bacilli carried in the urine tubercles and ulcers about the ureteral orifice appear and if the invasion is wide later fibrous shrinkage may reduce the capacity greatly It is to be assumed on pathological evidence that the renal lesions are bilateral but progressive destructive disease may be confined to one kidney

The symptoms include polyuria hematuria pyuria dysuria and strangury but at the inception renal tuberculosis usually is symptomless Similarly physical examination at the start may be entirely negative Later slight tenderness may be elicited on palpation of the kidney or in the upper lumbar region posteriorly Constitutional symptoms if any usually are slight The condition is to be suspected particularly in a patient with pulmonary tuberculosis in the presence of unexplained albuminuria hematuria or pyuria especially the last two even if the quantity of blood or pus is small Dysuria or cystitis not explained otherwise should always be investigated Examination of the urine may show small or moderate amounts of albumin an abnormal number of erythrocytes and pus cells Intensive search usually reveals the presence of tubercle bacilli (see Demonstrating Tubercle Bacilli p 253) Pyelography cystoscopy and ureteral catheterization are used to demonstrate the extent and location of the lesions

Specific chemotherapy generally accepted as the first treatment of renal tuberculosis is usually continued for two years or more Various drugs have been given concomitantly with good early results but a lengthy follow up of patients (J H Williams Jr Lattimer 1956 1957) indicates that the best regimens are those which include isoniazid and PAS possibly with the addition of streptomycin Among the cases treated early healing has been satisfactory remaining so after approximately five years In the more advanced cases with marked

destruction of tissue the relapse rate is apparently greater than 10 per cent and nephrectomy may be indicated The response to chemotherapy is judged by the rate of disappearance of abnormal elements from the urine It is particularly important by repeated cultures of the urine to note the time of disappearance of tubercle bacilli and their possible later reappearance

#### TUBERCULOSIS OF THE GENITAL TRACT

Genital tuberculosis was found in 1.7 per cent of 1143 autopsies on tuberculous subjects by Auerbach at the Seaview Hospital—14.4 per cent of the males autopsied and 10.4 per cent of the females It is almost always caused by blood borne infection from lesions elsewhere in the body In 41 cases in females Auerbach found the fallopian tubes involved in 97.5 per cent the uterus in 58.5 per cent and the ovaries in 31.7 per cent The cervix is seldom affected the vagina and labia rarely The most common sequel of salpingitis is localized or diffuse peritonitis Both tubes may be involved but the lesions are usually unilateral There may be few or no localizing symptoms if any they appear as dull vague pains in the lower abdomen accentuated perhaps during menstruation The menses may be scanty irregular or absent There may be slight or moderate leukorrhea tubercle bacilli may be found in the discharge or in the menstrual blood Curettage may bring away endometrial tissue revealing tuberculous changes in microscopic examination Pelvic and sometimes abdominal examination may reveal an elongated round mass a few centimeters in diameter in the pelvis The lesions may heal spontaneously if they are not extensive but if they are chronic surgical resection after a prolonged course of chemotherapy is favored sometimes to eliminate the focus and prevent extension to the peritoneum Exacerbations of the disease especially if the uterus is involved may be caused by pregnancy prolonged postpartum bleeding not otherwise explained should arouse the suspicion of tuberculosis Chronic or healed tuberculous salpingitis may cause sterility

Male genital tuberculosis usually is manifested first in the epididymis but pathological examinations suggest that the initial focus usually is in the prostate the epididymal lesion being a secondary extension In 105 cases examined at autopsy Auerbach found the prostate involved in 95.2 per cent the seminal vesicles in 61.9 per cent the epididymis in 48.5 per cent

and the testes in 29.5 per cent. Ljunggren found associated involvement of the kidneys in 50 per cent of 60 cases of tuberculous epididymitis. As the lesions progress extension to the opposite epididymis is common. The bladder also may be affected secondarily. Progressive disease may be followed by the establishment of sinus tracts perforating the scrotum and allowing the discharge of tuberculous pus to the outside.

The onset of *tuberculous epididymitis* may be insidious with the development of a nodular or diffuse infiltration and this may subside and remain latent for a time or it may be acute with rapid swelling of the epididymis possibly with a serous effusion in the scrotum. Later the testis may become swollen, painful and even undergo softening. Usually the acute inflammation subsides after several weeks leaving behind chronic lesions which may slowly progress. Examination then may reveal a thickened more or less nodular epididymis. If the testicle is involved it may be enlarged to twice or more its natural size. The vas may be thickened and nodular and rectal examination may reveal diffuse or nodular enlargement of the seminal vesicles and prostate. If any of the lesions have liquefied limited fluctuant areas may be palpable. If fistulas develop tubercle bacilli may be demonstrated in the discharging pus; they also may appear in the urine and the seminal fluid. While rest treatment is indicated in these cases the lesions usually run a chronic course and the prognosis for ultimate healing is not good. Prolonged chemotherapy, i.e. for a year or more using two specific drugs such as isoniazid and PAS in combination may bring about great improvement and arrest the infection. Usually the epididymis is excised if very necrotic, sometimes the testicle with it.

#### TUBERCULOSIS OF THE MENINGES AND CENTRAL NERVOUS SYSTEM

Tuberculosis of the meninges and central nervous system figures conspicuously among infected infants and children and is frequently the terminal event of fatal disease at this time of life. In adults meningitis is a relatively infrequent cause of death even among those who have suffered from chronic pulmonary disease. Occasionally however it is a terminal event due to hemic dissemination as resistance breaks down. While leptomeningitis is the commonest manifestation the dura may contain a few scattered tubercles or may become involved by extension from an adjacent bony focus such as vertebral caries.

Limited lesions usually cortical may appear also in the cerebrum less often in the cerebellum or spinal cord. In rare cases these may heal eventually with calcification. Such tubercles may be of a chronic granulomatous character gradually increasing in size and producing the clinical manifestations of tumor; the symptoms then depend on the location of the lesion.

Thus tuberculous meningitis may originate from a lesion previously established in the cortex, choroid plexus, pia or dura or may develop as part of an acutely disseminated infection from some more remote source. The distribution of the tubercles, the perifocal congestion and the fibrinous exudate are characteristically basilar. The regions favored are those about the circle of Willis, the interpeduncular space, the fissures of Sylvius and the optic chiasm. Tubercles may be located in and close to the walls of arteries. The contiguous brain tissue is edematous or infiltrated for a short distance.

The patient may present the clinical picture of generalized miliary tuberculosis for several weeks before meningeal symptoms develop. In other cases obvious chronic tuberculous disease may have been present usually in the chest. Not infrequently however the patient, especially if he is a child, previously may have appeared perfectly well. For no apparent reason the child becomes listless and irritable. The appetite fails and he loses weight. If he is too young to describe the headache it may be eloquently indicated as he feels or fumbles his head with his hands and by the sharp so-called "hydrocephalic cry" or the unmitigable and sustained scream of pain. Vomiting is common, usually sudden and often projectile; sometimes it is precipitated by a change of position in bed. The temperature may rise to 103° F. or more in the afternoon. At first the pulse may be quick, but later it becomes slow in proportion to the fever. The pupils initially are contracted later dilated. As the terminal or paralytic phase follows that of irritation the restlessness, night terrors and outcries may give way to stupor, whimpering and muttering. The patient may be disoriented and wander from his bed. There may be clonic contractions of single groups of muscles and not infrequently general convulsions. Photophobia is common and there may be strabismus and blepharoptosis. Monoplegia or hemiplegia may be observed. The initial constipation and urinary retention usually are followed by incontinence.

Early in the disease the neck and the

muscles of the back and extremities may be sore and stiff. Kernig's sign is usually positive. There may be general hyperreflexia, ankle and patellar clonus and a positive Babinski sign. Later the muscles may become flaccid and reflexes diminished. As the coma deepens the patient may execute athetoid movements. Finally he becomes completely motionless, the temperature varies widely and irregularly and sweating may be profuse. In this unconscious state his eyes half closed and jaw agape he weakly breathes away his final hours.

The natural duration of the disease varies from three to six or eight weeks. Occasionally deaths in children have been reported to occur in less than a week after the clinical onset. Actually the disease may exist some time before symptoms become manifest. Occasionally during the course of generalized miliary tuberculosis a routine spinal puncture may yield fluid containing tubercle bacilli. Spontaneous recovery is rare.

Lumbar puncture yields fluid which is usually clear and under increased pressure. Occasionally it is slightly turbid or xanthochromic. As the fluid stands in the tube a thin coagulum develops and tubercle bacilli may be found in this or in the sediment collected after centrifugation. Otherwise culture or guinea pig inoculation usually proves positive. The number of cells in the fluid usually is 25 or more per cu mm, lymphocytes predominating. The content of protein is found moderately or markedly increased, glucose is decreased.

Illingworth (1957) has reviewed his experience with diagnostic problems in miliary and meningeal tuberculosis in children and emphasizes the considerable number of cases in which the initial symptoms are vague, meningismus may be absent, the tuberculin skin test may be negative and the initial concentration of sugar in the cerebrospinal fluid may be 50 mg per 100 ml or more (14 per cent of his cases).

**Treatment.** Specific chemotherapy has greatly improved the outlook of patients afflicted with tuberculous meningitis so that today when the disease is diagnosed and treated in its early stages the prospect of recovery is approximately 90 per cent. When experiences of statistical value started accumulating in 1948 it became apparent that about 20 to 25 per cent of the patients treated with streptomycin or dihydrostreptomycin alone (intramuscularly and intrathecally) for periods of a few months could be expected to survive

two years or longer. Later the addition of PAS (orally and in some clinics intravenously) and the prolongation of such combined regimens for many months were found to improve the results substantially. Then the oral administration of isoniazid, which easily diffuses through normal tissue barriers into the cerebrospinal fluid in combination with streptomycin intramuscularly proved that almost all patients will survive at least for two years. Most experienced clinicians now consider it unnecessary to inject streptomycin intrathecally since during the acute inflammatory phase of the disease the drug enters the cerebrospinal fluid from the blood in quantities sufficient to be of therapeutic effectiveness; this also obviates the disadvantage of the local irritation caused by the drug when given intrathecally. Some add PAS orally to the other two drugs but it is not clear that this contributes any additional advantage.

In practice when treating adult patients isoniazid 8 to 10 mg per kg of body weight per day is given in two or three divided doses orally while streptomycin 2.0 gm daily is injected intramuscularly usually divided into two doses given eight or ten hours apart. The usual dose of PAS may also be given if desired. This regimen is continued up to six months, the results being judged by the subsidence of symptoms and the changes in the cerebrospinal fluid which in the early weeks should be estimated at least once a week. The glucose concentration is a good indicator of improvement as it rises to the normal level and the cells usually diminish more slowly. Isoniazid is continued at the same dosage until the patient is obviously recovering at which time it may be lowered to 5 mg per kg. Chemotherapy should be continued for at least a year but the dose of streptomycin may have to be reduced because of neurotoxicity. If vertigo or impairment of hearing is manifested the dose may be reduced after two to six months to 1.0 gm daily in some cases 1.0 gm three times weekly or 2.0 gm every third day has been considered sufficient. Des Autels and Pfuetze advocate continuing treatment for six months after the glucose and cells of the cerebrospinal fluid return to normal and prefer continuing until the protein is normal or at least falling consistently toward the end of a total of eighteen or more months of treatment. The purpose of prolonged treatment is to guard against a recurrence for this has been known to take

place as long as five years after the early recovery under short term therapy.\*

When the disease is not treated until it has reached a late phase the recovery rate is reduced to approximately 25 to 30 per cent. One of the complications which may develop in the late phase is blockage at the spinal subtentorial or basal cisternal levels from the accumulation of fibrous inflammatory exudate. It interferes with the circulation of fluid and may hinder the access of administered drugs to some areas of disease. Damage to the brain may result from abnormally increased intraventricular pressure especially in children. Injections of tuberculin (PPD) intrathecally have been used by Honor V. Smith and her associates at Oxford for the purpose of stimulating a reaction which may help to break down the blockage and to lower the barrier between the blood and the cerebrospinal fluid. A number of clinicians have administered one of the adrenal corticosteroids intrathecally to reduce the inflammatory reaction of the diseased meninges with the same end in view and have observed clinical improvement and a rapid lowering of the protein content of the fluid. These measures do not appear to be necessary in cases which are diagnosed early in the disease and treated properly with isoniazid and streptomycin.

Following recovery there may occasionally be some residual damage including motor palsies, deafness (due mostly to streptomycin or dihydrostreptomycin given intrathecally), mental impairment and abnormal behavior. These are very infrequent with present chemotherapy.

#### TUBERCULOSIS OF THE SPECIAL STRUCTURES

The breast may be infected by way of the blood stream but more often by extension from an adjacent lesion such as caries of a rib or tuberculous costal chondritis. The breast may be diffusely swollen and tender but more commonly localized irregular nodular swellings increasing in size appear in one or more of the segments. The conglomerate tubercles usually become

caseous leading to the formation of abscesses from which cutaneous fistulas may originate. The infection may burrow widely under the pectoral tissues. If not too extensive incision of the abscess followed by a course of combined chemotherapy may lead to healing. If the glandular tissue is extensively involved mastectomy may be indicated.

**Tuberculosis of the myocardium** while rare may occur through infection extending into it from the epicardium, less often from the mediastinal lymph nodes or from the blood stream. The lesions may be numerous and isolated or diffuse and caseous. Alphonse described tuberculous phlebitis of the myocardial veins. An extremely rare lesion is tuberculous endocarditis with valvular vegetations.

**Tuberculous arteritis** of peripheral arteries is also rare sometimes due to the lodgment of infected emboli.

**Tuberculosis of the hypophysis** is rare. Kirschbaum and Levy studied the chronic granulomatous type which may produce the symptoms of diabetes insipidus or of pituitary cachexia (Simmonds disease).

**Tuberculosis of the thyroid and the pancreas** is rare and is observed only in generalized infection or as an extension from an adjacent lesion. Chronic thyroiditis and less often chronic pancreatitis on a tuberculous basis are occasionally reported.

**Tuberculosis of the adrenals** if extensive produces the Addisonian syndrome which may be rapidly progressive and fatal. In these cases the adrenals are usually caseous. A few tubercles may be discovered in the adrenals in generalized miliary tuberculosis and rarely old calcifications may be found.

**Tuberculosis of the Liver** Isolated gray tubercles in the capsule or substance of the liver are not uncommon findings at the autopsy of patients who have died of pulmonary tuberculosis and they may be demonstrated in those who have never suffered from this disease. In subacute and chronic forms of generalized tuberculosis particularly in young children and in Negroes numerous caseous tubercles of various sizes may be found in the liver but extensive abscess formation is uncommon. Infection of the gallbladder or duct is also infrequent. It is usually due to extension from an adjacent focus which may be in the lymph nodes.

At Seaview Hospital Stemmerman found tuberculosis of the bile ducts in 3 per cent of 1500 autopsies on tuberculous subjects.

\*For tuberculous meningitis in children the following regimen is carried out in the Children's Medical Service of Bellevue Hospital: Streptomycin 1.0 gm intramuscularly for a minimum period of one month or until the cerebrospinal fluid glucose has been normal for one week thereafter 1.0 gm twice weekly isoniazid orally 10 mg per kg daily divided into two doses for four to six weeks then 7 mg per kg sulfone (Promazole) orally 0.25 to 0.5 gm daily for two years.

muscles of the back and extremities may be sore and stiff Kernig's sign is usually positive There may be general hyperreflexia ankle and patellar clonus and a positive Babinski sign Later the muscles may become flaccid and reflexes diminished As the coma deepens the patient may execute athetoid movements Finally he becomes completely motionless the temperature varies widely and irregularly and sweating may be profuse In this unconscious state his eyes half closed and jaw agape he wearily breathes away his final hours

#### DISEASES DUE TO ATYPICAL ACID FAST BACILLI

(Barnsdale Disease "Swimming Pool Disease" "Yellow Bacillus" Disease)

The study of mycobacteria from human sources was greatly stimulated by the introduction and use of specific chemotherapy

for tuberculosis and this in addition to increasing our knowledge of the true tubercle bacillus has contributed a large fund of information concerning "atypical acid fast bacilli." It has long been known that a vast number of mycobacteria dwell in soil and water and on vegetable matter and that some which are harmless to man cause disease in other species of animals. Hence when atypical organisms were found in the discharges of human subjects they were labelled insignificant Saprophytes such as *M. smegmatis* an inhabitant about human genitalia and *M. phlei* which may be ingested with food are noteworthy contaminants of certain specimens being searched for tubercle bacilli. Only in recent years however has it been appreciated how often actual disease in man may be induced by mycobacteria which in some of their characteristics seem to rank between *M. tuberculosis* and the saprophytes *M. fortuitum* was linked with human disease by Cruz in 1938 and *M. ulcerans* was reported in 1948 by MacCallum and his associates to be the pathogen in certain chronic ulcerative lesions of the skin. Later a number of observers reported cases of relatively benign papules and superficial ulcers of the skin which appeared usually on the elbows following abrasions incurred while the person was swimming in an artificial pool. In 1954 Linell and Norden published their study relating these infections to an organism which they called *M. balnei*.

While "atypical acid fast bacilli" have been implicated also in abscesses of lymph nodes they have been identified most often in recent times in connection with pulmonary disease. In several series of cases the organisms have been found in the sputum of several of every 100 patients admitted to hospitals for tuberculosis and other chest conditions. The pulmonary disease associated with these atypical mycobacteria may run a course closely resembling that of tuberculosis although it is usually less severe. A number of fatalities have been reported several of these in cases of associated silicosis. Pathologically the disease may be indistinguishable from tuberculosis with its caseous necrotic lesions and cavity formation. However the infection does not often become generalized is usually only locally invasive and has a tendency to heal spontaneously. Sometimes these mycobacteria have been found as secondary invaders of genuine pulmonary tuberculosis especially as it undergoes healing (Kelz Cotton and Lester). They may also appear similarly in cases of bronchiectasis and

usually the lesions were miliary or consisted of abscesses 10 to 20 mm in diameter

**Tuberculosis of the spleen** is a frequent sequel of hemic infection. A few or many miliary tubercles may be found in the capsule or in the parenchyma or the organ may be enlarged and infiltrated with large caseous conglomerates; the latter however is uncommon. Nodular calcifications sometimes may be demonstrated roentgenographically.

**Tuberculosis of the ear** usually is a complication of cavitary pulmonary disease. The middle ear may be infected through the eustachian tube. The process is subacute or chronic leading to abscess formation and slow perforation of the drum after which a chronic fistula often persists. Secondary infection then may occur. The mastoid may become involved but this is uncommon at least in serious degrees. The diagnosis is suggested by gradually increasing painless deafness, tinnitus and a feeling of fullness in the ear of a patient with cavitary pulmonary tuberculosis. Perforation of the drum is usually painless also. Tubercle bacilli may be demonstrated in the discharging pus. The inflammation occasionally heals without perforation of the drum leaving permanent partial deafness.

The nose may become involved in lupus vulgaris, the lesions of which may extend to the mucosa. Picking of the nose by a tuberculous patient is supposed sometimes to cause infection of the mucosa and development of a chronic perforating septal ulcer. Tuberculosis of the paranasal sinuses is observed rarely.

#### PREVENTION OF TUBERCULOSIS

The observations that some increase in resistance to tubercle bacilli may be conferred upon animals and that naturally acquired and limited tuberculous lesions have a similar effect in man have stimulated many attempts to develop means of prophylactic vaccination and passive transfer of immune bodies. Killed devitalized and attenuated bacilli have been tried as vaccines administered by various routes as have fractions and products of the bacilli and of the lesions caused by them. It has been shown that relative immunity may develop usually in slight degree after the administration of living or dead virulent or attenuated organisms. The duration of this may be a relatively few months or some years. Absolute protection against subsequent virulent infection has never been proved and no plan has justified itself thus

far for universal application. One of the better known vaccines BCG, an attenuated living strain of the bovine type of bacillus prepared by Calmette and Guérin, is proved to have an immunizing capacity and the degree of this is still under study. The reports of J. D. Aronson who conducted a test of BCG among large groups of American Indians and of R. G. Ferguson who vaccinated the personnel of hospitals and sanatoriums in Saskatchewan, Canada, are impressive because of the objective comparative methods used. The tuberculosis attack and fatality rates were lower by at least 75 per cent in the groups vaccinated than in the unvaccinated. For the better protection of groups especially the young who do not react to tuberculin and therefore have presumably not been infected and who are destined to have close and frequent contact with tuberculosis as in poor economic areas and in hospitals BCG has gained some favor. It is generally thought however that a natural primary infection if the lesion which it produces remains limited gives greater and longer lasting relative immunity than artificial vaccination.

An objection to the vaccines which are now available is the development after their inoculation into the body of tissue hypersensitivity which invalidates the usefulness of the tuberculin test for the detection of natural infection and the tracing of its source.

The administration of isoniazid to infected children to test its ability to avert the occasional serious sequelae of primary tuberculosis such as meningitis has been reported by the United States Public Health Service to have definitely favorable effects.

Measures which are assuredly effective for prevention include the following:

- Elimination of tuberculous animals and pasteurization of milk
- Improvement of living conditions and education in personal hygiene
- Adequate medical examinations to detect lesions in their incipency usually in the preclinical phase
- Sufficient and proper treatment of the early case to prevent excavation of the lesion and infection of "contacts"
- Isolation of the infectious case
- Rehabilitation of patients with arrested disease to prevent relapse

**Incidence and Epidemiology** Known of old throughout south Asia and Africa and almost epidemic throughout Europe in the eleventh to thirteenth centuries leprosy persists today in a patchy endemic zone encircling the world largely between the thirtieth parallels of latitude but also including Japan Korea south China and South Africa Outside of these areas it does not appear to be communicable Only a handful of cases remain in Scandinavia and none in most European countries In Spain and Portugal it is still increasing in incidence In the United States leprosy is endemic in those states bordering on the Gulf of Mexico and in Hawaii

Leprosy is so difficult to acquire that it was believed for many decades to be hereditary rather than contagious yet it is so easy to acquire that nearly half the new cases are unaware of having had any contact with the disease Perhaps this paradox can best be resolved by the view that leprosy is easily acquired by contact with lepromatous persons during transient periods of increased susceptibility to which some persons are subject Such susceptibility may be inherited though this is unproved

The determinants of susceptibility are not known Hawaiians have seventy times the leprosy morbidity experienced by Caucasians in Hawaii and similar racial differences are reported from many other areas Children are more susceptible other things being equal than adults A family history of leprosy probably means heightened susceptibility to infection though it is not necessarily associated with low resistance to the established disease Persons with a negative Mitsuda reaction to injected lepromin (see below) are more susceptible to leprosy and they are more apt to have the lepromatous form of the disease if they do become infected than persons with a positive reaction Diet is probably unimportant

**Morbid Anatomy and Clinical Features** Leprosy is a disease which principally involves the skin and subcutaneous nerves It occurs in reasonably well defined types in either of which the disfigurement and deformity may be produced by the disease process itself or by the consequences of the loss of sensation or motor or trophic innervation in an affected area or part The clinical picture may also be significantly modified in the lepromatous type by the development of systemic amyloidosis or by associated infection with tubercle bacilli Because of these very considerable differ-

ences between types and groups no single clinical description will usefully depict leprosy Consequently in the present discussion the principal attention will be devoted to defining the individual manifestations in themselves quite recognizable that serve to characterize the various forms of the disease

There are two principal types of leprosy the *lepromatous* (formerly called cutaneous) type in which the patient manifests no resistance to the disease and the *tuberculoid* (formerly called neural) type in which he manifests more or less vigorous resistance to it Most cases of leprosy fall into one or the other of these two categories Transition does occasionally occur from one to the other (most often from tuberculoid to lepromatous) and a case undergoing such transition may present features of both types Nevertheless no mixed form of leprosy as such is recognized

In addition to these two relatively stable "polar" types of leprosy two groups of leprosy cases are recognized the *indeterminate* (I) and the *borderline* or *dimorphous* (B) The types subtypes groups and subgroups are outlined in Table 1 and the principal distinctions among these types and groups are given in Table 2

Definitions of these types and groups adopted by the Sixth International Congress of Leprosy in Madrid in 1953 were as follows

**Lepromatous type (L)** A malign type especially stable strongly positive on bacteriological examination presenting more or less infiltrated skin lesions

**Table 1** Types and groups of leprosy with subtypes and symbols as approved by the Sixth International Congress of Leprosy at Madrid in 1953

TYPES	GROUPS
<i>Lepromatous</i> (L)	<i>Indeterminate</i> (I)
Macular	Macular (I <sub>m</sub> )
Diffuse	Pure neuritic (I)
Infiltrated	
Nodular	
Pure neuritic (?)*	
<i>Tuberculoid</i> (T)	<i>Borderline</i> (dimorphous) (B)
Macular (T <sub>m</sub> )	Infiltrated
Minor tuberculoid (T <sub>1</sub> )	Macular (?)*
Major tuberculoid (T <sub>2</sub> )	Pure neuritic (?)*

\* The bracketed question marks inserted by the Classification Committee of the Congress indicate that the queried categories have not yet been described in the literature

cancer of the lung and in chronic aspirational pneumonia complicating achalasia of the esophagus

Infection with these atypical strains may produce hypersensitivity to tuberculin although the skin test usually is only weakly positive. Similarly some of the strains when inoculated into animals induce not only a relative homologous immunity but also a relative heterologous immunity to other strains and to *M. tuberculosis* infections. The latter has been studied in connection with the vole bacillus which has been used as a vaccine for man.

The disease which does not have distinctive clinical features is identified by the isolation of the sole causative organism which Runyon, Buhler and Pollak and a number of other workers have observed most often to be a photochromogenic mycobacterium (cultures change from white or buff to a bright lemon yellow a few hours after exposure to a bright light according to Runyon). The organisms grow on artificial culture medium in a week or so at incubator temperature; they also grow at room temperature but less rapidly. Various cultural tests of virulence and growth on special media help to distinguish these mycobacteria from typical tubercle bacilli. As a rule the photochromes have little or no pathogenic effects when inoculated by the standard route into guinea pigs; mice may be susceptible and varied results have been noted in other animals.

A characteristic of these mycobacteria is their lesser susceptibility compared with *M. tuberculosis* to most of the specific anti-tuberculous drugs. Wolinsky, Smith and Steenken found these organisms resistant to streptomycin and para-aminosalicylic acid but somewhat susceptible to isoniazid, amithiozone and a thiocarbinide; they are also susceptible to cycloserine. This feature has been reported somewhat differently by others.

Other strains of nontuberculous mycobacteria have been designated by Runyon as nonphotochromogens and scotochromogens. These too have been found in the sputum and tissues of patients but they may be found also in healthy people and their pathogenic role is not clearly recognized. The taxonomy of these atypical organisms remains to be definitely determined.

#### LEPROSY

Leprosy is a chronic infectious and communicable disease caused by *Mycobacterium leprae*. Its principal clinical lesions occur in the cooler tissues of the body: skin, superficial nerves, nose, pharynx and larynx. The distal portion of the eye and the testicles may also be damaged. Disfigurement and deformity due to skin infiltration and peripheral nerve destruction of untreated patients may be extremely severe and conspicuous. The disfigurement is the principal reason for the fear and loathing historically—and tragically—attached to the disease.

**Etiology.** *Mycobacterium leprae* is the cause of leprosy. Discovered in 1873 by G. Armauer Hansen of Norway, it is an acid fast rod about the same size as *M. tuberculosis* from 15 to 60  $\mu$  long and 0.2 to 0.45  $\mu$  thick. It occurs in tissues singly in cigar bundle clusters and in oval aggregates 15 to 25  $\mu$  in diameter called globi. *M. leprae* cannot be cultivated on artificial media. Though many efforts have been made (notably by Danielssen in Norway and Mountz in Hawaii) to infect laboratory animals and even humans by injecting bacilli into them, only one (by Arming in Hawaii) has been successful and in it the possibility of prior infection of the subject by ordinary means could not be excluded. Apparent accidental inoculation of two Marines by tattooing was reported during World War II.

Table 3 Detailed comparison of the two "polar" types of leprosy

CLINICAL FEATURES	LEPROMATOUS	TUBERCULOID
Sites of election	Skin (and nerves)	Nerves (and skin)
Distribution	Generalized usually	Localized often
Type of lesion	Leproma or nodule	Macule and plaque
Visceral involvement	Widespread subclinical	Perhaps lymph nodes
Mucous membrane lesions	Regularly and early	Nose only infrequently
Eye involvement	Often late	Very rarely
Hypopigmented macules	Occasionally early many	Frequently few
Annular plaques	Sometimes	Frequently
Erythema multiforme or nodosum	In reactions often	Not seen
Fever	In reactions usually	Rarely
Eyebrow alopecia	Often	Not seen
Gynecomastia	Sometimes late	Not seen
Symmetry of involvement	Usual	Exceptional
Nerve enlargement	Slow and symmetrical	Rapid and asymmetrical
Nerve damage	Late often partial	Early often complete
Skin anesthesia	Late but inevitable often on extremities	Early and coextensive with skin lesions
Visceral damage	Testicle only	Not seen
HISTOLOGICAL FEATURES		
General pattern	Xanthoma like macrophages and histiocytes	Sarcoid like epithelioid cell tubercles and lymphocytes
Vacuolated lepra cells	Always	Rarely in reacting cases only
Giant cells	Occasional foreign body or Touton type	Often Langhans type
Lymphocytes	Few	Abundant
Lipoid	Abundant	Minimal
Necrosis	Rarely	Caseation rare in skin common in nerves
Nerve changes	Fibrosis structure well preserved	Obliteration of normal architecture
Visceral amyloidosis	Common late	Not seen
BACTERIOSCOPY		
Acid fast bacilli ( <i>M. leprae</i> )	Abundant except in long treated or burned out cases	Rare or lacking except during reactions never abundant
SPECIAL TESTS		
Lepromin (Mitsuda) reaction	Negative	Positive
Serological tests for syphilis	Biological false positive in half of cases	No false positives
Hyperglobulinemia	Usual	Exceptional
Erythrocyte sedimentation rate	Elevated especially during reactions	Usually normal
CLINICAL COURSE		
Course untreated	Progression fatal in 10 to 20 years usually	Spontaneous recovery as a rule in 1 to 3 years
Course treated with sulfones	Slow regression (3 to 8 years)	More rapid regression
Intercurrent tuberculosis	Common in untreated cases	Rare
Transition to other type	Rare even under treatment	Occurs in some severe and reacting cases
Contagiousness for others	Definitely established	Slight or nil
Disposition of case	Isolation necessary in endemic areas until bacilli disappear	Isolation unnecessary except during reactions

Table 2 Fundamental distinctions among the two types and two groups of leprosy cases.

	LEPROMATOUS Type	BORDERLINE Group	INDETERMINATE Group	TUBERCULOID Type
<b>Clinical Features</b>				
Character and prognosis	Stable and progressive	Unstable either progressive or regressive	Unstable often regressive may progress to either polar type	Stable benign, usually regressive
Skin lesions	Lepromas papular or nodular*	Plaques often annular	Pale or pink macules	Pale macules or raised plaques often annular
Nerve damage	Slow and symmetrical	Generally more rapid than in lepromatous symmetrical	Usually only slight and symmetrical	Sudden severe asymmetrical
Bacterioscopy	Abundant bacilli	Many bacilli	Few bacilli if any	Usually no bacilli except during reactions and in nerves
Histology	Xanthoma like	Sarcoid like but with some lipid filled cells dimorphous	Banal round-cell infiltration	Sarcoid like
Lepromin reaction	Negative	Negative or weakly positive	Negative or weakly positive	Positive often strongly so

\* Except in Lucio's pure diffuse lepromatous leprosy in which no lepromas occur. This form is very rare out side of Mexico and Costa Rica.

and negative to lepromin. The peripheral nerve trunks become manifestly involved as the disease progresses habitually in symmetrical fashion and often with neural sequelae in advanced stages.

**Tuberculoid type (T)** Usually benign markedly stable generally negative on bacteriological examination presenting in most cases erythematous skin lesions which are elevated marginally or more extensively positive to lepromin. Sequelae of peripheral nerve trunk involvement may develop in a certain proportion of cases and this may give rise to serious and disabling deformity. This frequently appears to occur as a result of extension from or through cutaneous nerve branches rather than of systemic dissemination and consequently it is often asymmetrical and unilateral.

The tuberculoid type was subdivided (Table 1) into *macular* ( $T_m$ ), *minor tuberculoid* ( $T_i$ ) and *major tuberculoid* ( $T_T$ ) subtypes characterized by flat pale anesthetic macules, pebbled erythematous slightly raised plaques and markedly elevated and thickened erythematous plaques respectively. The T variety is precisely that originally known as "maculoanesthetic." Wade believes that it should still be so designated on the ground that patients with such flat lesions have not developed enough resistance to warrant being classified as tuberculoid.

**Indeterminate group (I)** A benign form relatively unstable seldom bacteriologically positive presenting flat skin lesions which may be hypopigmented or erythematous, the reaction to lepromin negative or positive. Neuritic manifestations more or less extensive may develop in some cases which have persisted as of this group for long periods. The indeterminate group consists essentially of "simple

macular" cases. These cases may evolve toward the lepromatous type or the tuberculoid type or may remain unchanged indefinitely.

**Borderline (dimorphous) group (B)** A malignant form very unstable almost always strongly positive on bacteriological examination with the lepromin reaction generally negative. This group may arise from the tuberculoid type as a result of repeated reactions and sometimes evolves to the lepromatous type. The nasal mucosa is generally bacteriologically negative. The skin lesions are usually seen as plaques, bands, nodules etc. with a regional distribution similar to that of lepromatous leprosy except for [usually but not always] conspicuous asymmetry. The ear lobes are likely to present the appearance of lepromatous infiltration. The lesions frequently have a soft or succulent appearance and their periphery slopes away from the center and does not present the clear cut well defined margins seen in the tuberculoid type; the lesions are therefore liable to be mistaken for lepromas. The surface of the lesions is generally smooth with a shiny appearance and a violaceous hue sometimes (in light skins) with a brownish (sepia) background.

A detailed catalogue of the many contrasts between the two polar types of leprosy—lepromatous and tuberculoid—is given in Table 3.

**Reactions** More or less transitory states of exacerbation or reactivation known as reactions may occur once or repeatedly in all forms of leprosy. In lepromatous leprosy these are known as *lepra reactions* and two principal forms are recognized. The ordinary lepra reaction consists of aggravation of existing skin lesions development of new ones and usually fever, neuralgia and malaise or prostration lasting for hours, days or weeks. This may or

FIG 34 Lepromatous leprosy of ulnar nerve at the elbow (A) with normal nerve (B) cut at same level for comparison. Note characteristic preservation of fairly normal architecture. The great thickening is due chiefly to thickening of the fibrous sheaths (Arnold H L Jr. *Modern Concepts of Leprosy*. Springfield Illinois: Charles C Thomas 1953.)

single edged safety razor blade is inserted 3 or 4 mm deep into a pinched up fold of involved skin or even uninvolved skin e.g. an ear lobe. It is then rotated about an axis perpendicular to the skin surface so that its edge scrapes the side of the cut and a small drop of tissue pulp and lymph is obtained. Blood does not interfere seriously. This drop is deposited (not spread thin) on a clean slide dried and stained by the Ziehl-Neelsen method destaining with preferably Gabbett's solution. The carbol-fuchsin should be used cold not warm for fifteen minutes. The preparation should not be subjected to decolorization too long because *M. leprae* is much less acid fast than *M. tuberculosis*.

The standard Ziehl-Neelsen staining pro-

cedure is not sensitive enough to be used on paraffin sections of tissue if bacilli are at all scarce. Wade's modification of the Fite-Faraco stain (Am J Path 28:157 1952) should be used to prevent defatting the bacilli.

In the absence of bacilli a suspicion of leprosy needs confirmation by demonstration of nerve damage. Such damage may consist of anesthesia or anhidrosis (usually coextensive with a skin lesion in tuberculoid cases) often on feet or hands in lepromatous; thickening of superficial nerves; muscular weakness or atrophy especially in the face and hands or histological changes in a biopsy specimen.

Leprous neuritis often produces sensory dissociation similar to that seen in syringomyelia. Sense of touch may be preserved but that of heat and cold or pain or both may be lost. Each should be tested separately. Palpation of the great auricular nerves where they cross the sternocleidomastoid muscles of the ulnar nerves just above and behind the internal humeral epicondyles or of the peroneal nerves behind the heads of the fibulas may reveal thickening, nodularity, stiffness or tenderness any or all of which are extremely suspicious of leprosy neuritis. Drooping of one or both lower eyelids or oral commissures or weakness or elevation of one eye brow may disclose the patchy weakness of facial muscles which Monrad Krohn has said is the most distinctive single neuro-

FIG 35 Tuberculoid leprosy of great auricular nerve. The nerve was almost 1.0 cm thick (normally 2.0 or 3.0 mm). Histologically there was complete obliteration of normal architecture with replacement by epithelioid cell tubercles and some caseation necrosis (Arnold H L Jr. *Modern Concepts of Leprosy*. Springfield Illinois: Charles C Thomas 1953.)

FIG 32 Lepromatous leprosy in a young boy. Note symmetrical involvement and predilection for cooler acral parts: brows, ears, nose, cheeks, chin, and fingers. Of interest also are madarosis (loss of eyebrows) and the burn scar on his anesthetic left hand (Arnold H. L. Jr. *Modern Concepts of Leprosy*, Springfield, Illinois, Charles C. Thomas, 1953).

FIG 33 Annular plaque of major tuberculoid ( $T_x$ ) leprosy which is verging on the borderline (B) variety as is shown by the loss of sharpness and steepness of the outer margin. Such a lesion is usually anesthetic (Arnold H. L. Jr. *Modern Concepts of Leprosy*, Springfield, Illinois, Charles C. Thomas, 1953).

may not be accompanied by erythema multiforme of either the ordinary or bullous variety. If as frequently happens it takes the form of erythema nodosum, the reaction is referred to as erythema nodosum leprosum; this pattern is most often seen during sulfone therapy and is generally believed to carry with it a relatively good prognosis in regard to the leprosy.

In tuberculoid or borderline leprosy reactions consist of aggravation of previous lesions or the appearance of succulent elevated new plaques, painful swellings of nerves may occur. *M. leprae* may become quite numerous in the lesions, and the lepromin reaction may decrease in intensity. Fever and constitutional symptoms (including erythema multiforme) do not occur in tuberculoid cases.

**Diagnosis.** An advanced case of leprosy with the combination of skin lesions and obvious nerve lesions should be readily recognized by the reasonably alert physician. It is in the early cases in which the nerve involvement is not readily apparent that the diagnosis of leprosy may be missed. In certain forms of the disease the diagnosis can be definitely established by demonstration of the presence of *M. leprae* in material

obtained from the patient's lesions. It is important to realize, however, that a clinical impression or suspicion of leprosy as such cannot be excluded by any one diagnostic procedure. A suspicion of lepromatous leprosy can be excluded by finding no acid-fast bacilli in the lesions, but such a negative finding will not exclude the indeterminate or tuberculoid variety. A suspicion of tuberculoid leprosy can be eliminated by excluding all evidence of nerve damage in the lesions, but such a finding will not exclude the indeterminate or lepromatous type.

Nasal scrapings, though they will show acid-fast bacilli in perhaps one third of early lepromatous cases and in all advanced ones, may be either positive or negative in either type of leprosy and cannot be relied upon either to confirm or to exclude the diagnosis. Nonpathogenic acid-fast diphtheroid bacilli indistinguishable from *M. leprae* may be found even in a normal nose.

A simple and trustworthy method of looking for bacilli in skin lesions is Wade's "scraped incision" procedure. The point of a scalpel or better still the corner of a

are outlined in Table 4. The duration of treatment in tuberculoid cases is determined by the clinical response since bacilli are usually lacking from the start. A clinically satisfactory result is likely to require a year or two. In lepromatous cases treatment is continued until the skin lesions and nasal mucosa are healed and virtually devoid of acid fast bacilli—usually at least two or three years in early cases and perhaps as long as six or eight years in heavily involved cases. Maintenance therapy for prevention of relapse is still an unsettled question. Ericson has shown that it is necessary for some lepromatous cases and it is probably advisable for most. Patients with a strongly positive reaction to lepromin however usually remain well indefinitely without maintenance therapy.

Reactions are mild and infrequent with small doses of sulfones. Moderate overdosage may cause headache, anorexia, nausea, dizziness, insomnia or tachycardia. Anemia which may occur at any dose level is the commonest potentially serious reaction and should be watched for by hemoglobin determinations weekly and later monthly. Toxic psychosis, agranulocytosis, hematuria or erythema nodosum may be seen with larger doses of any sulfone and require interruption of treatment or reduction of the dose.

In the event of complete intolerance for even small doses of sulfones, amithiozone is probably the best substitute. The dose is 25 mg a day initially increased slowly to a maximum of 100 to 150 mg a day by mouth. Dihydrostreptomycin 10 gm intramuscularly three times a week is much less effective according to most observers though controlled studies over short periods in the Philippines and South Africa under Doull's direction suggest that it is almost as good as the sulfones. Isoniazid and para-aminosalicylic acid are not reliable in their effects upon the disease.

During lepra reactions bed rest is indicated and acetylsalicylic acid and anti-histaminics may be helpful. The sulfone

dosage must be sharply reduced as a rule. Erythema multiforme, ordinary or bullous or erythema nodosum may be controlled with corticotropin or adrenal steroids in the usual doses.

Keratitis, iritis or iridocyclitis may occur in lepromatous cases and may require treatment with 1 per cent hydrocortisone drops or oral hydrocortisone or prednisolone. Atropinization is indicated for iridocyclitis. In advanced cases eyelid paralysis may lead to exposure keratitis.

Although lepromatous neuritis is slowly progressive, tuberculoid leprosy neuritis may cause rapid swelling of one or more nerve trunks sometimes with such intense and persistent pain as to require surgical decortication of the nerve involved. Nerve abscesses which occur rarely may require incision and drainage.

Orthopedic procedures aimed at rehabilitation of patients with claw hand resulting from ulnar neuritis or foot drop from peroneal palsy differ in no essential respect from those devised for similar lesions due to other diseases.

Social, psychological and economic rehabilitation may present the most difficult and surely the most important problem of all. A physician who must deal with even a single case of leprosy should read Perry Burgess' *Who Walks Alone and Born of Those Years*. He should also read George Fites' article entitled *Leprosy Society and Hansen's Disease* in the October-December 1956 issue of the *International Journal of Leprosy*. Fear of leprosy is where you find it and it is not necessarily eradicated by education. Nevertheless it is the physician's responsibility to relieve fear of the disease in the patient and the family so far as he can by calm and sympathetic explanations—and when the patient is well to do what he can to help him resume as nearly normal a life as possible.

**Prevention.** Prevention of leprosy involves primarily the recognition and isolation of bacteriologically positive cases in endemic areas. Home isolation may well be ade-

Table 4. Principal antileprosy drugs and their dose schedules

	INITIAL DOSE	USUAL MAXIMUM DOSE	ROUTE
4,4'-Diamino diphenyl sulfone (Avlosulfon [Ayerst])	25 mg 2 or 3 times per week	100 mg per day 500 mg per week (in oil)	Oral or intramuscular Intramuscular
Sulfoxone sodium (Diasone [Abbott])	0.3 gm 3 to 6 times per week	1.0 gm daily	Oral only
Glucosulfone sodium (Procrin [Parke-Davis])	0.5 gm 3 to 6 times per week	1.0 to 5.0 gm per day	Intravenous only

logical sign of leprosy Contracture of a fifth finger or flattening of a hypothenar or thenar eminence or the grooving produced by atrophy of the interosseous muscles of the hands may betray the presence of leprosy ulnar or median neuritis Actual claw hand deformity or foot drop may ultimately occur

Biopsy of a thickened great auricular nerve or of other skin nerves which subserve no important motor function is a practicable procedure of value if a diagnostic biopsy of skin is not possible The histological changes are usually characteristic and in tuberculoid leprosy bacilli are much more readily found in the nerves than in the skin

Röntgenograms of hands and feet may show concentric absorption of phalangeal or metatarsal shafts a characteristic "trophic" lesion which leads ultimately to loss of continuity of the bone and shortening of digits or of the whole foot Rarely diabetic peripheral neuritis may produce such changes but without anesthesia Dropping off of digits is a myth

Painless trophic plantar ulceration identical with that seen in *tabes dorsalis* and in *syringomyelia* may also occur Such ulcers are not primarily leprosy and no bacteriological or histological evidence of leprosy is to be found in them They often lead to osteomyelitis of metatarsal bones

**Histamine Test** A depigmented macule unless it is an actual scar is never a manifestation of leprosy A hypopigmented macule however may be If such a macule is not anesthetic to heat or cold or to touch or pain and no other evidence of nerve damage is found and no bacilli are present then the most sensitive tests of nerve damage should be applied before concluding that the lesion is not leprosy The simplest of these is the histamine test A shallow pinprick is made through a drop of 1:1000 histamine phosphate solution inside or at the edge of the macule The flare around the resulting wheal will be lacking inside a leprosy macule In deeply pigmented skins this test is difficult or impossible to interpret and the Mecholyl sweating test may be used This can be done by injecting 0.1 ml of 1 per cent methacholine chloride solution intradermally inside or at the margin of the macule and observing by any of several techniques the distribution of the resulting sweat response Sweat glands within a leprosy macule will not respond If they fail to respond in the normal surrounding skin as well the result is obviously inconclusive

**Lepromin Test** The lepromin test is performed by the intradermal injection of 0.1 ml of a boiled or autoclaved gauze filtered suspension of *M. leprae* and human tissue prepared by grinding lepromatous granulation tissue in a mortar and suspending it in saline solution Mitsuda reported in 1919 that such an injection was followed by no reaction in patients with lepromatous leprosy but that in tuberculoid cases an inflammatory nodule resulted reaching its height in about three weeks and sometimes ulcerating Fernandez later described a forty-eight hour Mantoux-like reaction fairly well correlated with the Mitsuda response A positive lepromin reaction does not denote the presence of leprosy It is positive in roughly half the population in many areas in which leprosy does not even occur It apparently denotes resistance to leprosy Its high correlation with a positive Mantoux reaction especially in persons without leprosy and the regularity with which BCG vaccine causes negative Mitsuda reactors to convert to positive suggest a relationship with exposure to tuberculosis which has not yet been explained or even fully evaluated The use of BCG vaccine to protect susceptible contacts against leprosy is now undergoing extensive experimental testing especially in South America

**Prognosis** Without treatment patients with lepromatous leprosy tend to suffer steady progression of their disease and to die of tuberculosis amyloid nephrosis in recurrent infection or leprosy within about fifteen years from the time the disease is first recognized Patients with tuberculoid leprosy untreated tend to recover completely except for residual nerve damage within a year or two if only one or a few annular plaques are present If their skin lesions are numerous and widespread the disease may run a rather protracted course with repeated relapses but the patient will still tend to recover completely if the lepromin reaction is strongly positive

**With chemotherapy** virtually all patients experience immediate arrest of the disease and steady improvement Recovery (except for residual nerve destruction) is usually complete in a year or two if bacilli were initially few or absent or in three to perhaps six or eight years if bacilli were initially abundant and the lesions widespread

**Treatment** The sulfones have almost entirely replaced chaulmoogra oil and its esters in the specific chemotherapy of leprosy The dosage and method of administration of the most commonly used sulfones

**Symptoms and Course of the Disease Anemic Form (Oroya Fever)** The incubation period is believed to be fourteen to twenty one days. In severe cases the onset is sudden with intermittent fever ranging to 104° F. progressive pallor, emaciation, prostration, rapid pulse and dyspnea. Muscle and joint pains, nausea, vomiting, diarrhea, headache and insomnia are also common symptoms, and delirium and coma are apt to be terminal manifestations. A petechial cutaneous eruption occasionally appears during the febrile period. The erythrocyte count may fall from normal to less than 1 000 000 per cu mm in four or five days, more rapidly than in any other condition exclusive of actual hemorrhage. Examination of alcohol fixed Giemsa stained blood films shows bartonellae in the erythrocytes in large numbers, 90 per cent of the cells frequently containing from one to fifty or more organisms (Fig. 36). Many reticulocytes and nucleated erythrocytes are present in the blood. In the severe form of the disease the mortality is 90 to 95 per cent. Secondary infection particularly with organisms of the salmonella group has been emphasized as an important factor in fatal cases. The average duration of this anemic stage of the disease is from one to three weeks; occasionally the condition of the patient remains critical for a period of eight to ten weeks. Convalescence is accompanied by a disappearance of the organisms from the erythrocytes and rapid blood regeneration, but blood cultures may be positive for many months after apparent recovery.

**Cutaneous Form (Verruga Peruviana)** This form of the disease, characterized by cherry red, hemangioma like cutaneous nodules, may follow the severe anemic form or may occur in patients who have had no previous symptoms. Intermediate cases are also frequently seen in which there is moderate anemia with rare bartonellae in the erythrocytes, slight or no fever, and only a few days of malaise followed weeks or months later by the typical cutaneous eruption. The appearance of the cutaneous nodules may be immediately preceded by a few days of moderate fever with joint pains.

The cutaneous nodules (verrugas) are commonly 2 to 10 mm in greatest diameter but range up to 3 or 4 cm. They may be single or extremely numerous. These are most numerous on the head, hands, feet and lower arms and legs, and are rare on the thighs, abdomen or lower chest. Occasionally they are seen in large numbers on

the mucous membrane of the mouth and pharynx. They are ovoid or spherical and usually half buried in the subcutaneous tissue and covered with thin bluish epidermis which often breaks down leading to ulceration and secondary infection. Healing occurs with little or no cicatrization after a period of several weeks. The cutaneous stage has no mortality *per se*. The possible complications are hemorrhage and local secondary infection, neither of which is apt to be serious.

**Diagnosis** The diagnosis is made from a history of residence in an infected area and on the clinical pictures. Finding bartonellae in the erythrocytes in blood films establishes the diagnosis in the anemic stage. In the cutaneous stage a nodule may be excised and bartonellae may be demonstrated in the endothelial cells. Blood cultures in *Leptospira* medium are positive in both stages. Rarely the cutaneous nodules may appear a year or more after an eventful visit to an infected area. Yaws, which may simulate verruga peruviana, can be differentiated by the demonstration of the specific organism.

The anemia is of the macrocytic type and the color index may be greater than one. The erythrocytes increase in both volume and hemoglobin content but since the increase in volume is proportionally greater the anemia is classified as hypochromic. Anisocytosis, poikilocytosis and polychromatophilia are constantly present. Normoblasts are numerous and megakaryoblasts are usually present. Reticulocytes may constitute more than 50 per cent of the erythrocytes. The leukocyte count is variable but often high and many imma-

FIG. 36. Carrion's disease. Giemsa-stained blood films showing *Bartonella bacilliformis* in erythrocytes. Both bacillary and coccoid forms are seen.

quate especially if children are not concerned. Bacteriologically negative persons—and any cases outside of endemic areas—apparently constitute little or no risk to others and need not be isolated. If home isolation is not practical bacteriologically positive patients should either move to a nonendemic area for treatment or (in the continental United States) be admitted to the U. S. Marine Hospital at Carville, Louisiana.

There is evidence that persons with a positive lepromin reaction run much less risk of acquiring leprosy than persons with a negative one. It may well be that one should perform BCG vaccination upon lepromin negative persons if they are exposed to leprosy in order to induce a positive skin test. Experimental evidence suggests that the induced positive test is accompanied by resistance just as the naturally positive one is.

Isolation should be maintained until the patient is bacteriologically negative or virtually so. Most leprosy institutions have established policies in regard to the requirements for release of patients from isolation.

### Bartonellosis

(Carrion's Disease, Oroya Fever, Verruga)

**Definition.** Carrion's disease is a specific arthropod-borne infection caused by a minute rickettsia-like microorganism and characterized clinically by an acute febrile anemic stage (Oroya fever) followed several weeks later by a nodular cutaneous eruption (verruca peruviana). Either of these stages may be inconspicuous or apparently absent and for this reason the

two clinical pictures were originally regarded as separate diseases.

**Distribution and Epidemiology.** The disease has been found chiefly in narrow valleys in the Andes Mountains at altitudes between 2000 and 9000 feet. It has been largely confined to Peru with a few cases in Ecuador and Bolivia, but in 1939 a serious outbreak was reported in Colombia suggesting that the distribution may be more widespread than has been supposed. The distribution of the disease corresponds in general to the habitat of its probable sandfly vectors *Phlebotomus noguchii* and *P. verrucorum*, but in Colombia lice and ticks have been suggested as vectors. Many natives of the infected areas have asymptomatic infections revealed only by blood culture. Severe epidemics in Peru have often been associated with the importation of railroad workers from noninfected regions. A reservoir for the infection in lower animals has been suspected but not found.

**Etiology.** The etiological agent was first seen in the erythrocytes in the anemic form of the disease by Barton in 1909 and was named *Bartonella bacilliformis* by Strong and his coworkers in 1915. It was cultivated in Noguchis leptospira medium by Noguchi and Battistini in 1926. Noguchi's original evidence of the etiological identity of Oroya fever and verruga peruviana was further confirmed by new methods of approach by the Harvard 1937 Expedition to Peru and the unity of the two conditions must be considered as established.

Rats, dogs, and a number of other mammals suffer from latent bartonella infections which after splenectomy evolve into a severe anemia comparable to Oroya fever. Cutaneous lesions do not occur in lower animals. Except for the transmission of human bartonella infection to monkeys, each species of bartonella appears to be completely specific for the species of animal from which it is recovered.

**Morbid Anatomy.** Postmortem studies of fatal cases of the anemic form of the disease show pallor, enlargement of the spleen and lymph nodes, and a megaloblastic hyperplasia of the bone marrow. The endothelial cells lining small vessels in the lymph nodes, spleen, liver, bone marrow, adrenals, kidneys, and many other organs are packed with small bacillary and coccoid organisms (bartonellae), often occurring in clusters. Microscopically the cutaneous nodules have the appearance of rapidly growing capillary hemangiomas. Bartonellae may be demonstrated within the endothelial cells with suitable technique.

## THE MYCOSES

### Actinomycosis

**Definition** Actinomycosis is a chronic granulomatous infection caused by *Actinomyces* *bovis*. The disease is characterized by the development of numerous abscesses which break down and develop multiple sinuses.

**History** In 1877 Bollinger found the ray fungus in a disease of cattle known as "lumpy jaw". It was named *Actinomyces* *bovis* by Harz. J. Israel in 1878 discovered the disease in man and pointed out the identity of the two infections. Lord in 1910 demonstrated that *Actinomyces* pathogenic for guinea pigs could be found in the gums and tonsils of apparently normal persons.

**Etiology** Actinomycosis is widely disseminated and is the most common of the highly fatal mycoses. The disease occurs most frequently in males.

**Mycology** The organism occurs in pus or tissues as lobulated or spherical granules which vary in size from minute particles to forms about 1 mm in diameter. Pure cultures are readily obtained from material aspirated from unopened abscesses but isolation is difficult from draining sinuses because of the overgrowth from contaminating bacteria. *Actinomyces* *bovis* is anaerobic and grows best at 37°C in glucose agar in a zone 5 to 10 mm below the surface.

**Immunology** Not much is known about the serological reactions of patients with actinomycosis.

**Pathology** Actinomycosis may develop in any part of the body. A granulomatous lesion is produced which is surrounded and intersected by new connective tissue. The local lesions spread by direct extension through the connective tissue rather than by way of the lymphatics, although metastatic lesions appear in various parts of the body as a result of showers of infected emboli.

**Clinical Manifestations** The clinical symptoms vary somewhat depending upon the part of the body involved.

**Cervicofacial actinomycosis** accounts for more than 50 per cent of all instances of the disease. Infection takes place through

the mucous membranes of the gums, mouth, pharynx or larynx. The whole infected area becomes indurated or "wooden" in consistency and extends beyond the apparent area of inflammation. The overlying skin has a dark red or purplish color and a lumpy uneven surface. As the infection spreads to the surface, multiple sinus tracts appear. With internal extension, the bones of the skull and even the meninges and brain may be involved. Trismus develops when the muscles of mastication are involved and dyspnea when there is pressure on the larynx. The lymph nodes of the neck usually are not involved. Pain is not a prominent feature and the patient's general health is not much affected so long as the disease remains localized in the area of the face and neck.

**Thoracic actinomycosis** occurs in about 15 per cent of the cases and produces cough, sputum, increasing dyspnea, slight fever, loss of weight and strength, night sweats, pallor and emaciation. The sputum contains blood in about half the cases and sometimes a fatal hemoptysis occurs. Pleural pain is common and effusions not infrequent. After the disease has reached the pleura it usually involves the thoracic wall, extends through the subcutaneous tissues and produces localized areas of induration with suppurating foci and multiple sinus formation. There may be extension to the mediastinum, esophagus and pericardium.

**Abdominal actinomycosis** is found in 20 to 30 per cent of the cases and represents a highly fatal form of the disease. The earliest signs are usually in the ileocecal region and are associated with the development of an indistinct, irregular mass which is not painful as a rule and shows no characteristic features. This may be the first manifestation of the disease or it may be preceded or accompanied by fever, chills, night sweats, intestinal colic and vomiting. As the disease progresses, there is usually involvement of the liver and spleen and symptoms of cystitis and pyelonephritis may appear. Jaundice may be present. Involvement of the central nervous system may occur in the terminal stages.

ture forms are usually seen. The plasma volume is increased.

The blood bilirubin is usually moderately increased but neither hemoglobinemia nor hemoglobinuria is present even in the severely anemic cases.

**Treatment** In the acute febrile form of the disease penicillin streptomycin chloramphenicol and tetracycline have all been used individually with apparently good results. The criteria for effectiveness are a rapid fall in temperature to normal levels and the disappearance of the bacillary forms of *Bartonella* from the circulating erythrocytes within forty-eight hours. Cocoid forms may persist several days longer. Evaluation of chemotherapeutic results is rendered difficult by the small number of cases in each series and by the fact that treatment has usually been initiated at a relatively late stage when it is difficult to exclude the possibility of spontaneous improvement.

At present writing the effectiveness of chloramphenicol (average dosage 17 gm. in five days in divided doses) seems best documented. It should be noted that Cuadra believes this drug to be effective primarily because it cures or prevents the concomitant or subsequent salmonella infection (which he believes to be the most important cause of death) while Urteaga and Payne stress the resulting rapid disappearance of *Bartonella* from the blood followed by a prompt reticulocyte response. Chloramphenicol may be given intravenously in comatose patients. Chemotherapeutic treatment of salmonellosis and other secondary infections should be guided when possible

by blood cultures and drug susceptibility tests and the calculated risk of bone marrow depression by chloramphenicol should be kept in mind. Iron should be given during convalescence.

Transfusions should be given when indicated by the clinical picture and by critically low erythrocyte counts and hemoglobin levels. General symptomatic and supportive treatment including the control of electrolyte balance in severely ill patients is obviously important.

The cutaneous stage rarely requires treatment except for general cleanliness. Excision of large necrotic secondarily infected nodules occasionally may be indicated but probably does not improve the final cosmetic result.

**Prevention** Fine mesh screening (25 to 30 squares per inch) and DDT are most effective against the sandfly. These measures are most important during the night when sandflies are active.

## Blastomycosis

**Definition** Blastomycosis is a chronic granulomatous disease which may be confined either to the skin or lungs or disseminated throughout the body

**History** The disease was first described by Gilchrist in 1894 and by Gilchrist and Stokes in 1896. It is found frequently throughout the western hemisphere but only sporadically in Europe. It is usually called American blastomycosis or Gilchrist's disease and should not be confused with European "blastomycosis" which is caused by *Cryptococcus neoformans* (*Torula histolytica*).

**Etiology** Blastomycosis is prevalent in the Chicago area, Louisiana, Tennessee, North Carolina and other parts of the country. The disease is nine times as frequent in males as in females.

**Mycology** The morphological studies of Conant and the serological investigations of Martin show that all strains of *Blastomyces dermatitidis* are morphologically and antigenically identical. Sputum, pus or biopsy material should be streaked heavily on Sabouraud's slants and on blood agar plates which contain antimicrobial drugs. The slants are kept at room temperature but the blood agar plates should be incubated at 37°C. The primary growth may be slow and cultures should be watched for two or three weeks. On blood agar the colonies are small, waxy and wrinkled and when emulsified in water and examined fresh under the microscope show typical budding, double-contoured yeastlike forms (7 to 10  $\mu$ ) identical in appearance with those found in the lesions.

**Immunology** Many patients acquire a sensitivity to the products of *B. dermatitidis* and give a skin test analogous to the tuberculin reaction. Martin found that patients with extensive involvement usually show a positive complement fixation when the whole yeast organism or certain of its extracts are used as the antigen. The test is negative when the lesions are small or well localized and becomes negative in the systemic cases after recovery.

**Pathology** The primary skin lesions may be of a superficial verrucous type with little ulceration or gummatous with open craters. The multiple subcutaneous abscesses found in the systemic type of blastomycosis are analogous to cold abscesses in tuberculosis. When the disease spreads from the skin, bones or other organs to the lungs it produces the appearance in the roentgenogram and at necropsy of a miliary hematogenous tuberculosis.

The characteristic budding organisms are found in the giant cells in the granulation tissue between the cells and about the edges of the necrotic areas.

**Clinical Manifestations** Cutaneous blastomycosis occurs most frequently on the face, neck or extremities. The primary lesion usually begins as a small reddish papule or papular pustule which slowly increases in size and is soon capped with a crust. There is epithelial hyperplasia giving the lesion a verrucous appearance. Minute epidermal abscesses appear about the edges of the lesions and some lesions break down to form deep craterlike ulcers with hard raised edges. The subjective symptoms are mild; pain is minimal and the patches are not sensitive to pressure. The regional lymph nodes usually are not enlarged and the general health of the patient is not impaired so long as the disease is confined to the skin.

**Systemic Blastomycosis** Patients with primary pulmonary blastomycosis have fever, night sweats, loss of weight, cough, sputum which is frequently bloody, leukocytosis, increased erythrocyte sedimentation rate and physical and roentgenographic evidence of extensive pulmonary disease. The lesion usually is incorrectly diagnosed as pulmonary tuberculosis but it may be mistaken for primary bronchogenic carcinoma. Sinus formation is rare as long as the disease is confined to the lungs but in the systemic cases in which there are multiple lesions of the bones and involvement of the internal organs it is frequent and characteristic.

**Diagnosis** Cutaneous blastomycosis is readily diagnosed by its characteristic lesions but the diagnosis should be confirmed by finding the organisms in the pus expressed from the small abscesses in the edge of the lesion by culture or by biopsy. In the systemic form the organisms can usually be grown from the sputum or from pus aspirated from a subcutaneous lesion. A positive complement fixation reaction is diagnostic but a negative result does not eliminate the possibility of the disease.

**Prognosis** The prognosis is good in cutaneous blastomycosis but poor for the pulmonary and systemic forms of the disease. Martin and Smith found that 92 per cent of the patients with the generalized form of the disease had died within two years. The prognosis in the pulmonary form can be improved by early diagnosis and prompt and adequate treatment.

**Treatment** The introduction of stilbamidine and 2-hydroxystilbamidine has revolu-

**Diagnosis** The diagnosis is based on the clinical syndrome the finding of the sulfur granule in the exudate or lesion or the cultivation of the organism. Biopsies of the sinus tract should be made when direct examination of the exudate fails to show granules. Frequent and repeated study of the exudate both in fresh preparations and with the Gram stain is imperative. Cultures are reliable in the yeastlike mycoses but not in actinomycosis. The cervicofacial forms must be differentiated from glanders, tularemia, tuberculosis and osteomyelitis. The pulmonary form simulates tuberculosis, pulmonary abscess, tularemia and other mycoses. The abdominal form may be mistaken for chronic appendicitis, amebiasis, typhoid fever, carcinoma of the intestines, tuberculosis, liver abscess, psoriasis, abscess and sarcoma of the retroperitoneal tissue or of the iliac bones.

**Prognosis** The prognosis is best in the localized skin and cervicofacial types and becomes progressively worse with the thoracic, abdominal, generalized and neurological types.

**Treatment** The general resistance of the patient should be supported as in tuberculosis by rest in bed and good food supplemented by vitamins and fruit juices.

Penicillin is the most effective drug for the treatment of actinomycosis. The sulfonamides are almost as good and can be substituted for penicillin when the patient is discharged from the hospital for a six month period of continuous therapy. Potassium iodide should be given concurrently with sulfonamides during the convalescent phase of therapy. The broad spectrum antimicrobial drugs are effective but are expensive and dangerous when administered for weeks or months. Surgical evacuation of pus, necrotic bone and destroyed lobes is an essential part of therapy.

## Nocardosis

**Definition** Nocardiosis is a chronic granulomatous disease caused by *Nocardia asteroides* and related species.

**History** This organism was isolated by Eppinger in 1890 and called *Cladothrix asteroides*. Subsequent isolates by other workers were called *Streptothrix*, *Actinomyces* or *Proactinomyces* thereby creating the confusion of names in the older literature.

**Mycology** The organism occurs in pus or tissues as gram positive branching filaments which are usually acid fast. Unlike *Actinomyces*, *Nocardia* grows readily on all usual laboratory media at either room or incubator temperature under aerobic conditions.

**Pathology** Abscess formation occurs earlier and somewhat more frequently in nocardiosis than in actinomycosis.

**Clinical Manifestations** The clinical picture may be identical with that of actinomycosis but primary involvement of the cervicofacial area and the abdominal organs is somewhat less frequent and infections of the lungs and feet more frequent. The course of the disease is usually more fulminating and small pulmonary lesions often metastasize to the brain.

**Prognosis** The prognosis is very grave unless the infection is diagnosed correctly and treated promptly.

**Treatment** Penicillin is not effective even in daily doses of 10 000 000 to 20 000 000 units. In contrast sulfadiazine and other sulfonamides seem to be specific. Four to 60 gm of sulfonamide should be given daily to obtain blood concentrations of 8 to 12 mg per 100 ml. The broad spectrum antimicrobial drugs are palliative rather than curative but may be necessary to control secondary infections. Surgery and iodides are not often required but should be used when indicated.

may be found anywhere in the south western United States and appears to be spreading eastward. Thousands of soldiers in army camps in the Southwest contracted the benign primary infection and a few of them developed severe granulomatous disease five to eight years after the initial infection. The disease occurs at all ages from three months to seventy years but is most prevalent between the ages of twenty, five and fifty five. In one series of 211 cases 83 per cent of the patients were males.

**Etiology.** The causative agent is *Coccidioides immitis*. Emmons has shown that the organism is present in rodents in the endemic area and Davis, Smith and Smith isolated the fungus from the soil. The organism may be introduced into man through a scratch or abrasion of the skin although the more usual method is inhalation which produces an atypical type of bronchopneumonia. The disease is not transmitted directly from man to man but laboratory infections occur frequently from the accidental inhalation of arthrospores from cultures.

**Mycology.** *Coccidioides immitis* multiplies in the tissues by endosporeulation. The organism is a spherule with a thick hyaline capsule varies from 11 to 70  $\mu$  in diameter and contains from 10 to 200 endospores. When infected tissues, sputum or other discharges are planted on Sabouraud's medium the endospores germinate and grow out as mycelia.

**Immunology.** All strains of *C. immitis* apparently contain identical antigens. During the course of the primary infection the patient exhibits precipitins and complement fixing antibodies and the skin becomes sensitive to coccidioidin. The precipitins and complement fixing antibodies disappear after recovery but the skin sensitivity like that to tuberculin is relatively permanent.

**Pathology.** In chronic coccidioidomycosis the organisms are surrounded by epithelial cells, giant cells, lymphocytes and plasma cells. Abscess formation is more frequent than in tuberculosis especially in the bones and subcutaneous tissues. Abbott and Cutler described three types of meningeal lesions: one is practically identical with tuberculous meningitis, a second has larger more granulomatous lesions and the third shows a thick accumulation of plastic exudate.

**Clinical Manifestations.** In some areas in the southwestern United States positive skin tests with coccidioidin have been found in 50 to 84 per cent of the population indicating that primary infection with *C. immitis* is common but usually asymptomatic.

When the reaction to infection is severe enough to be recognized as a disease the symptoms, signs, roentgenographic changes and course of the disease parallel that of primary tuberculous infection. The patients have malaise, anorexia, chills, fever, headache, backache, night sweats and pleurisy. The cough produces a scant amount of mucoid or mucopurulent sputum which contains the characteristic spherules of *C. immitis*. The organisms have been found in pleural fluid. Roentgenograms of the lungs may show thickening of the hilar region, peribronchial thickening or patches of nodular or bronchial pneumonia. The larger, more solid lesions may break down and leave thin walled cavities which usually heal in a few weeks or months but may persist for years. Sensitivity to coccidioidin appears after seven to fourteen days and skin lesions resembling those of erythema nodosum or erythema multiforme develop in 20 per cent between the fifth and fourteenth days of the disease and persist for one to four weeks. This form of the disease has been known for years as "valley fever," "desert fever," "San Joaquin fever" or "the bumps." Although recovery is usually rapid and complete an occasional case passes into the progressive virulent type of the disease with involvement of bones, subcutaneous tissues and internal organs including the brain.

Sometimes the organism gains entrance through the skin or possibly through the tonsils. Lesions of the cervical lymph nodes have been described which simulate those of tuberculous adenitis.

**Diagnosis.** One should suspect coccidioidomycosis in any obscure disease originating in a native of the endemic area and in persons who have visited such areas. *Coccidioides immitis* can be found in the sputum in the primary infection. In the progressive type the organisms are present in the sputum in the subcutaneous abscesses and in the lesions of the internal organs. In progressive coccidioidomycosis there is a steady increase in the complement fixing antibodies while the skin sensitivity decreases or disappears.

Coccidioidomycosis must be differentiated from tuberculosis, syphilis, glanders, bacterial osteomyelitis, epithelioma and other mycoses.

**Prognosis.** The prognosis is excellent in primary pulmonary involvement, good in the dermal and lymph node types of the disease when they are a part of the primary infection but most grave in the generalized and meningitic types.

tionized the therapy of blastomycosis. Most of the previously incurable systemic infections can be cured and the response of the other types is more rapid than with the older vaccine iodide regimen. Sulbamide is the more toxic of the two drugs. Most systemic cases can be cured with maximum daily doses of 225 mg of hydroxystilbamidine a day for thirty days or with alternate periods of ten days of treatment and ten days of rest until the total dose of 8 to 12 gm has been administered. The dose of 225 mg should be diluted in 300 ml of physiological saline or in 5 per cent glucose in distilled water and administered intravenously over a three hour period. The drug should be protected from daylight both during preparation and during administration to prevent the development of toxic degeneration products.

Relapses do occur as long as six months to two years after an apparent cure. In most instances the relapses have occurred in patients with necrotic bone lesions or in other areas which are not adequately drained. Another course of hydroxystilbamidine should be started and surgical drainage instituted. If a second relapse occurs the new fungicidal drug amphotericin (Fungizone [Squibb]) should be tried (see Coccidioidomycosis).

Cutaneous blastomycosis usually responds satisfactorily to local roentgen therapy when given simultaneously with potassium iodide and subsequently to desensitization of the sensitive patient.

## Geotrichosis

The bronchi and lungs and occasionally the mouth and intestinal tract may be attacked by one or more species of the genus *Geotrichum*. The oral lesions resemble those of thrush and the pulmonary infection simulates blastomycosis. Usually the pa-

tient has symptoms of bronchitis or of a rather mild but chronic type of bronchopneumonia. In the more severe forms of the disease blood may be present in the sputum and cavities develop in the lungs. The *Geotrichum* is frequently a secondary invader in chronic klebsiella (Friedländer's bacillus) infection of the lungs and occasionally in tuberculosis.

**Mycology** The organism grows readily on Sabouraud's medium at room temperature and at 37° C. There is a budding form of *Geotrichum* which is readily confused with the budding form of *Blastomyces* but this budding form is always accompanied by the rectangular conidia which are characteristic of the genus.

**Treatment** The oral lesions respond to the gentian violet treatment described for *Candida albicans*. The intestinal form should receive oral doses of gentian violet in salol-coated capsules in doses of 32 mg three times a day. The bronchial and pulmonary forms have a good prognosis when treated with an autogenous vaccine and oral potassium iodide. Resistant cases should be given a trial with amphotericin (see Coccidioidomycosis).

## Coccidioidomycosis

**Definition** Primary coccidioidomycosis is an acute infection with a good prognosis but may develop into progressive coccidioidomycosis which is a generalized granulomatous disease with a high mortality.

**History** Posadas and Wernicke recognized the disease in Buenos Aires in 1892. Rixford reported a case from California in 1894 and Rixford and Gilchrist studied a series of cases in 1896. In 1900 Ophuls and Moffitt cultivated the organism and demonstrated that it was a fungus and not a protozoan.

**Incidence** The disease is encountered most frequently in southern California but

throughout the world. The organism has been isolated from fruit juices, milk from cows with mastitis and from pigeon manure.

**Mycology** *Cryptococcus neoformans* grows readily on Sabouraud's medium, the initial colonies appearing after four to twelve days incubation at 37° C. The colonies are medium in size, soft, mucoid with a creamy color. On examination the oval or slightly elongated cells 5 to 10  $\mu$  in diameter are surrounded by large capsules which are outlined clearly in India ink preparations. This fungus multiplies by budding; it does not form ascospores or mycelium. There are several immunological types as determined by capsular swelling with specific serums.

**Immunology** Patients usually exhibit no precipitins, agglutinins or complement fixing antibodies, but filtrates from cultures have given positive skin tests of the delayed type.

**Pathology** Mook and Moore described acneiform pustules, granuloma-like ulcers, deep-seated abscesses and nodules which may increase in size and simulate "myxomatous tumors." Giant cells and foam cells are numerous; fibroblasts, lymphocytes and plasma cells are present, but there is a remarkable paucity of polymorphonuclear leukocytes. In several instances the tissue reaction was similar to that seen in Hodgkin's disease. The encapsulated organisms are present both in and outside of giant cells, but there is an almost complete absence of leukocytes.

**Clinical Manifestations** The patient may present single isolated abscesses, subcutaneous tumor-like masses or multiple subcutaneous abscesses as in the original case of Busse and Buschke. The primary pulmonary lesions resemble those of primary carcinoma or reinfection tuberculosis.

In the more common cerebral type of infection the onset is insidious with headache, dizziness, vertigo and stiffness of the neck. Occasionally the onset is sudden with violent and excruciating headache and vomiting. The patient has little or no fever and the pulse and blood pressure remain normal. The disease often is mistaken for a rather chronic type of tuberculous meningitis. After several weeks or months more severe symptoms and signs appear, such as neuroretinitis, papilledema, strabismus, nystagmus, ptosis, diplopia, ataxia or hemiplegia. The patient ultimately becomes comatose and dies of respiratory failure.

**Diagnosis** The dermal, subcutaneous and lymph node lesions may be diagnosed by

routine biopsies and cultures on Sabouraud's medium. The diagnosis of the pulmonary forms is made by growing the organism from the sputum. In the meningeal form of the disease the cerebrospinal fluid pressure is increased and the fluid usually contains 200 to 800 cells per cubic mm, which are chiefly mononuclear. The cerebrospinal fluid sugar is decreased. The cryptococci are present in small numbers and are readily mistaken for erythrocytes or lymphocytes. After centrifugalization the sediment from the fluid should be planted on Sabouraud's medium and watched for three or four weeks. Not infrequently the organism can be found by direct examination if a drop of the sedimented material is mixed with India ink.

**Prognosis** The prognosis is grave in all forms of the disease, especially the cerebral form, which until recently has been considered inevitably fatal.

**Treatment** A number of patients have been treated with the new fungicidal drug amphotericin (see *Coccidioidomycosis*). Except in moribund cases the immediate results have been dramatic following the intravenous administration of this antimicrobial. Some patients have remained well for as long as two years.

## Histoplasmosis

**Definition** Histoplasmosis resembles coccidioidomycosis in having a benign primary pulmonary phase and a less common severe generalized form which involves the reticuloendothelial system.

**History** In 1906 Darling in Panama found round or oval parasites which he thought were protozoa in the endothelial cells and monocytes of certain cases of splenomegaly. Dodd, Tompkins and De Monbreun in 1934 isolated *Histoplasma capsulatum* from a typical clinical case in a child and discovered that the parasite was a fungus.

**Treatment** Most primary pulmonary infections heal rapidly in a few weeks without specific treatment. The primary cases which have persistent thin walled cavities present a difficult problem. If symptoms persist for more than six months the infected area should be removed by segmental lobectomy.

The generalized and meningeal infections are very difficult to treat however the new fungicidal drug amphotericin offers some hope for these unfortunate patients. Amphotericin is available in two forms one for intravenous and one for oral therapy. The initial dose of the intravenous preparation is 0.25 mg per kg of body weight and the dose is increased by 0.25 mg every two or three days up to 1.0 mg per kg. The drug is dissolved in 1.0 liter of sterile 5 per cent glucose in distilled water and administered by intravenous drip over a six hour period. Heparin may be added to reduce thrombosis of veins. Acetyl salicylic acid and antihistaminics should be administered at the beginning of the injection to minimize the slight febrile reactions which sometimes accompany or follow the injections. The treatment should continue for at least thirty days and sometimes for two to three months.

The oral treatment has not been standardized. The dose will vary with the purity of the preparation. All seriously ill patients should have the intravenous injections initially.

## South American Blastomycosis

South American blastomycosis is a chronic granulomatous disease quite similar in its clinical course to coccidioidomycosis.

At present the disease is confined to South America where De Almeida has collected the reports of 255 cases. The portal of entry is frequently in the area about the mouth and there is ulceration of the in-

testinal tract and adenopathy severe enough to suggest Hodgkin's disease.

The organism is found in the tissues as a large (10 to 30  $\mu$ ) round doubly contoured form with multiple small buds about the periphery which were originally mistaken for endospores. It grows readily on Sabouraud's medium and on blood agar. Conant found that the method of growth and budding on blood agar was more like that of *Blastomyces dermatitidis* than of *Coccidioides immitis*.

The disease is usually fatal.

Sulfadiazine in daily doses of 2 to 4 gm results in dramatic temporary improvement. Amphotericin should be given a trial in this disease (see Coccidioidomycosis).

## Cryptococcosis

(Torulosis)

**Definition** Cryptococcosis is a subacute or chronic highly fatal infection which may involve any part of the body but has a marked predilection for the brain and meninges.

**History** In 1894 Busse and Buschke isolated from a fatal case with multiple lesions of skin and viscera a yeastlike organism which they called *Saccharomyces* but which has now been definitely identified as *Cryptococcus neoformans* (Torula histolytica). This disease is called blastomycosis in the European literature and European blastomycosis in America to distinguish it from American blastomycosis or Gilchrist's disease which is caused by *Blastomyces dermatitidis*.

**Etiology** Cryptococcosis occurs in all parts of this country and in scattered areas

## Candidiasis

**Definition** *Candida* may produce acute or subacute infections of the mouth vagina skin nails bronchi and lungs and occasionally a septicemia endocarditis or meningitis

**History** The organism now known as *Candida albicans* was discovered in oral thrush by Langenbeck in 1839

**Etiology** The disease is found in all parts of the world at all ages in all races and in both sexes Oral thrush is most common in infants and in patients with wasting diseases Pregnancy and diabetes predispose to vaginal candidiasis Dermal lesions occur in bakers waiters fruit packers bartenders and housewives whose hands are macerated from frequent soaking in water Poorly fitting artificial teeth predispose to infections of the tongue and mouth

Benham isolated both pathogenic and nonpathogenic strains of *Candida* from normal skin and showed by animal experiments that *C. albicans* is the only pathogenic species

**Mycology** *Candida* grow readily on Sabouraud's medium after two to four days in cubation at room or incubator temperatures The colonies are soft moist oval white structures which have a distinct yeastlike odor *Candida albicans* is lethal for rabbits ferments certain sugars agglutinates in specific serums and forms typical chlamydospores on corn meal agar

**Immunology** Many normal persons have agglutinins in their blood and a positive skin reaction while some patients with active infection have neither

**Pathology** Both budding cells and mycelial threads may be found in sputum and in scrapings from the dermal and mucosal lesions

**Clinical Manifestations** *Candida* may produce thrush vaginal candidiasis paronychia onychia intertriginous candidiasis dyshydrosiform eruptions generalized eruptions and chronic glossitis Certain of these entities notably thrush and glossitis may be encountered in chronically ill patients who have been receiving prolonged antimicrobial therapy The precise relationship of the chemotherapy to the furtherance of the *Candida* infection in such situations has not been established

**Bronchitis** both the acute and chronic varieties results from bronchial infections The symptoms resemble those of bacterial bronchitis but the sputum usually is mucoid or gelatinous

**Pneumonitis** occurs as an acute or subacute process The lungs may show massive patchy consolidation in one or more lobes There is cough malaise fever and leukocytosis but usually the patients are less toxic than with bacterial infections The sputum is mucoid or mucopurulent and may contain blood

**Diagnosis** The diagnosis is established by cultivating and identifying the potentially pathogenic *Candida* (*Monilia*) *albicans* *Candida* is frequently a secondary invader in tuberculosis pulmonary abscess bronchiectasis neoplasm and even other types of mycoses

**Prognosis** The pulmonary and septicemic forms may be fatal The bronchial and localized infections are often chronic and resist treatment but rarely kill the patient

**Treatment** Bronchial and pulmonary moniliasis should be treated with potassium iodide In some cases the patients have positive skin tests to *Candida* vaccines and may not respond to the iodides until partial desensitization with vaccine has been effected The severe chronic generalized infections of skin nails and intestines in children have resisted all known forms of therapy The new fungicidal drug amphotericin should be tried in these cases since the fungus is susceptible to this drug in the test tube

The acute oral lesions usually respond to alkaline washes or to gargles with 1:10,000 gentian violet Recently a jelly like preparation of sodium propionate has been found very effective in curing *Candida* vaginitis

## Sporotrichosis

**Definition** Sporotrichosis is a chronic infection characterized by the formation of gumma like nodules abscesses and ulcers The lesions usually are confined to the skin and superficial lymph nodes

**Etiology** Histoplasmosis occurs throughout the world and in all parts of the United States but appears in greatest concentration in the Central Mississippi and the Ohio River valleys. All races are susceptible and both sexes are attacked at all ages but adult males seven times as frequently as females. Children seem to be relatively more susceptible than to other mycotic infections and male and female children are infected in equal numbers. Spontaneous histoplasmosis has been found in dogs, rats, mice and skunks. The organisms grow in profusion in pigeon, bat and chicken dung and the inhalation of these dried materials has given rise to epidemics of histoplasmosis.

**Mycology** The organism can be isolated directly from the blood, sputum, sternal bone marrow or from tissues at necropsy by planting the material in dextrose agar or dextrose broth at 37° C. Two types of colonies appear, one of them a mycelial type and the other a yeastlike type.

**Pathology** Primary pulmonary histoplasmosis appears as multiple small discrete spots in the lungs with associated infection and enlargement of the tracheobronchial lymph nodes. As healing occurs the organism disappears and the central portions of the lesions become caseous and later calcify. In rare instances, as shown by Dublin, the primary infection behaves like a primary progressive tuberculosis and kills the patient. Johnson has found several cases which showed the multiple calcification that is characteristic of healed primary infections in which reinfections have occurred with the development of cavities and of pulmonary fibrosis.

*Histoplasma capsulatum* is an intracellular parasite which in progressive cases invades the entire reticuloendothelial system.

**Clinical Manifestations** The benign primary pulmonary infections are usually asymptomatic. Infections beginning in the mouth, larynx, pharynx and ears show local necrotic ulcerations and definite enlargement of the regional lymph nodes. The progressive form of the disease is characterized by splenomegaly, hepatomegaly, emaciation, irregular pyrexia, leukopenia and anemia. Not all patients present this complete syndrome; the liver and spleen may not be enlarged; the disease may be confined chiefly to the lungs or even to the skin as in the case studied by Hansmann and Schenken.

**Diagnosis** The disease should be sus-

pected in every obscure infection in which there is enlargement of the lymph nodes with or without accompanying enlargement of the liver and spleen. In most instances within a few weeks after the initial infection the patient has a tuberculin-like allergy which can be demonstrated by the intracutaneous injection of 0.1 ml of a 1:1000 dilution of a standardized histoplasmin. The reaction is read after forty-eight to seventy-two hours in the same way as a tuberculin reaction and has a similar significance. Most rapidly progressive cases never develop a histoplasmin reaction and terminal cases which formerly reacted may become anergic.

Complement-fixing antibodies appear in the serum of patients with progressive infections and increase in titer as the disease progresses.

*Histoplasma capsulatum* shares a small amount of common antigen with *Blastomyces dermatitidis*, resulting in cross reactions both to the skin tests and to the complement fixation. However, no confusion will arise if both tests are performed simultaneously. C. E. Smith has found cross reactions to histoplasmin in patients with *Coccidioides immitis* infections although the reactions were always less in extent than to coccidioidin.

**Prognosis** The prognosis is excellent with the primary pulmonary forms, dubious in the localized infections and almost hopeless when the infection is generalized.

**Treatment** The new fungicidal drug amphotericin shows great promise as a therapeutic agent in histoplasmosis (see *Coccidioidomycosis*). Several patients with acute generalized infections and one with meningitis improved rapidly after treatment. The chronic reinfection type of disease improves slowly but progressively. Some patients, as in tuberculosis, will require resectional surgery.

## Maduromycosis

### (Madura Foot)

Maduromycosis or mycetoma is a chronic infection affecting principally the foot but in rare instances other parts of the body. It is characterized by multiple abscesses and sinuses and the development of granulation and connective tissues.

Mycology Carter in 1860 proved that the disease was a mycosis and introduced the term "mycetoma" or fungous tumor. The disease may be caused by any one of thirteen species of the genus *Nocardia* or any one of nineteen species of molds belonging to two classes and eight genera (Gammel).

**Etiology** The specific cause is contained in the white yellow deep brown or black granules which appear in the discharges from the affected region. The disease is most common in males and in farmers or other persons who come directly in contact with the soil.

**Pathology** The pathological reaction is essentially the same regardless of the type of invading fungus. There is local and general swelling of the parts affected with a corresponding degree of deformity. In old chronic cases the skin is darkened and the surface studded with pitted scars, open sinuses and nodular fungating elevations. Dense masses of scar tissue are found in the healing lesions. The abscesses connected with the sinuses are filled with mucoid fluid in which the characteristic granules are floating.

**Prognosis and Treatment** Sulfonamide therapy may cure the type of maduromycosis which is caused by *Actinomyces* or *Nocardia*. The disease does not heal spontaneously and the patients eventually die of secondary infection unless the infected limb is amputated.

## Chromoblastomycosis

Chromoblastomycosis or verrucous dermatitis is characterized by the formation of warty cutaneous nodules which through slow progressive growth become transformed into prominent papillomatous vegetations which may or may not ulcerate. Usually the lesions are confined to the feet and legs but may be limited to the hands and arms. In 1911 Pedroso of Sao Paulo, Brazil, isolated a pigmented organism from patients with verrucous lesions of the skin which was later named *Hormodendrum pedrosoi*. Large spherical bodies dark brown in color are present in abundance in the verrucous lesions and grow readily on Sabouraud's medium.

**Pathology** The disease is chronic and may last for years. With the development of extensive fibrosis in the deeper dermal lesions the lymphatics are blocked and the patient suffers an elephantiasis of the extremity.

**Treatment** Complete destruction of the lesion by surgical excision or electrotherapeutic methods would seem to be logical when the disease is diagnosed in its incipient stage. Surgical amputation is not justifiable because the lesions rarely become severely infected and usually make sufficient response to medical treatment to leave the patient with a useful limb. The internal treatment consists of large doses of potassium iodide up to as much as 10 to 90 gm per day. Iontophoresis with copper sulfate was used with considerable success in the case reported by Martin, Baker and Conant.

 Powell R. E. A Survey of Chromoblastomycosis in Queensland. *Australian J Dermat* 1:214 1952.

**History** Schenck in 1896 isolated a fungus later identified as *Sporotrichum* by E. F. Smith from a patient in Johns Hopkins Hospital. The second case was described by Hektoen and Perkins in 1900 who named the fungus *Sporotrichum schenckii*. The disease was recognized in France in 1903 by de Beurmann and Raymond and their organism was named *Sporotrichum beurmanni* by Matruchot and Raymond.

**Etiology** The disease occurs throughout the world but most often in males especially farmers, laborers and horticulturists. The primary lesion was on some part of the upper extremities in 90 of 102 cases. Sporotrichosis occurs spontaneously in horses, dogs and rats. Meyer infected himself while working with an equine strain. Plants may be the primary host.

**Mycology** The yeastlike tissue form of the organisms will grow on Francis glucose cystine blood agar at 37° C in five to ten days. The white moldlike form grows on Sabouraud's medium at room or incubator temperature after five to ten days and slowly becomes brown or black on further incubation.

**Immunology** Agglutinins and complement fixing antibodies may appear in the serum and occasionally a tuberculin like sensitivity develops in the patient.

**Pathology** The gumma like nodules usually consist of a central abscess surrounded by granulation tissue with giant and epithelioid cells and a peripheral zone of connective tissue histologically resembling syphilitic tuberculous or other chronic inflammations. In the living tissue *Sporotrichum* occurs as oval bodies of fairly uniform size 2 to 3  $\mu$  broad and 3 to 5  $\mu$  long.

**Clinical Manifestations** The primary lesion usually is in the skin and may appear as early as twenty days or as long as three months after the initial infection. The primary lesion is a hard spherical elastic movable subcutaneous nodule not adherent to the overlying skin. It becomes attached to the skin which first becomes pink and then purplish and finally black and necrotic. This lesion (sporothrix chancre) may persist for months. Usually after a few days or weeks multiple subcutaneous nodules appear along the course of the lymphatic drainage. These nodules are at first freely movable but later adhere to the overlying skin, become reddened and ulcerate through to the surface discharging a small amount of thin pus. The

lymph vessels between the nodes may become so thickened they can be felt as hard cords.

De Beurmann and Gougerot classified the clinical types of the disease as (1) lymphatic (2) disseminated (3) epidermal (4) sporotrichosis of the mucous membranes (5) skeletal sporotrichosis and (6) visceral sporotrichosis. In the rare disseminated gummatous form single or successive crops of nodes develop at intervals. Pulmonary sporotrichosis with cavitory lesions in the lungs is being found with greater frequency.

**Diagnosis** The diagnosis is established by cultivating the organisms from the discharges or from material removed at biopsy. The disease may simulate syphilis, tuberculosis, blastomycosis, cryptococcosis, glanders, tularemia, leprosy or pyogenic infections.

**Prognosis** Uncomplicated sporotrichosis is rarely fatal when untreated. It persists for months or years but appropriate treatment usually is followed by healing.

**Treatment** Potassium iodide should be given in slowly increasing doses up to 4 to 6 gm or more daily. If absorption of closed abscesses is slow they may be punctured, aspirated and injected with a weak solution of iodide. Incision and curettage are to be avoided. Ulcerated lesions may be painted with tincture of iodine and dressed with a solution containing water 500 ml, potassium iodide 10 gm and iodine 10 gm. The treatment should be continued for at least a month after apparent recovery. Some of the generalized visceral infections respond incompletely to potassium iodide therapy. These should be treated with hydroxystilbamidine (see Blastomycosis) or amphotericin (see Coccidioidomycosis).

## Aspergillosis

Certain species of *Aspergillus* especially *Aspergillus fumigatus* produce inflammatory granulomatous lesions in the skin external ear vagina nasal sinuses orbit bronchi lungs and occasionally bones and meninges. The disease was first recognized by Bennett in 1842 and the first careful necropsy of pulmonary aspergillosis in man was by Virchow in 1856. Renon's monograph published in 1897 established the frequency and importance of aspergillosis in France.

Extensive pulmonary lesions may occur in instances in which there are overwhelming exposures to the spores as in pigeon feeders hair cleaners and certain agricultural workers. Two chronic forms of pulmonary aspergillosis can be recognized. The first appears as a migrating pneumonitis of the allergic type and the second results in the development of dense round sharply circumscribed balls which vary in diameter from 1 mm to 5 cm and in number from one to ten or more. *Aspergilli* grow readily on dextrose agar or Sabouraud's medium at either room temperature or at 37°C. Infection may be suspected from the greenish or brown color of the discharges. *Aspergilli* are frequently secondary invaders or accidental contaminants and the diagnosis should not be made exclusively on the appearance of the organism on culture. One should demonstrate the mycelial forms directly in the discharges before the material is planted.

The standard treatment is with potassium iodide. If hypersensitivity to an autogenous *Aspergillus* vaccine can be demonstrated then vaccine therapy is also indicated. The migrating allergic type of aspergillosis frequently improves following the administration of autogenous vaccines made from the fungus and from all bacteria isolated from the sputum to which the patient gives a positive skin test. The solid ball-like lesions should be removed surgically by wedge resections.

## Penicilliosis

Several species of the genus *Penicillium* are capable of producing lesions in the ear and skin and occasionally in the lungs. Clinically the infections resemble those caused by the *Aspergillus* and the same care has to be exercised in establishing the etiological relationship between the culture and the disease. The treatment is the same as for aspergillosis.

## Mucormycosis

The first authentic case of mucormycosis in man was reported by Paltauf in 1885. The disease is being recognized with increased frequency at the present time.

Mucormycosis may be caused by any one of the three genera *Mucor*, *Absidia* or *Rhizopus* which make up the order *Mucorales*. The infection occurs most often in patients with uncontrolled diabetes, leukemia or myeloma and in patients treated with corticosteroid hormones or broad spectrum antimicrobial drugs.

The infection begins most often in the orbit or sinuses but may start in the lungs or intestines. The organisms grow in the walls of the blood vessels and cause death by metastases to the brain and other vital organs.

The treatment is directed to restoring the patient's resistance to normal by controlling the diabetes and removing the deleterious hormones or clinical agents. Theoretically immunity might be increased with heat-killed vaccines made from the patient's own organism as employed by Harris in the first clinical cure of mucormycosis. Surgical excision of the focus of

fection has become sufficiently intense to result in metastatic lesions in the skin and mucosa

Less precise knowledge is available concerning the length of time during which detectable reagin will persist in the serum of persons who receive no treatment. It is probable that the serological tests for syphilis once positive do not spontaneously revert to negative for at least ten years. Whether spontaneous serological reversal occurs in a significant number of patients (exclusive of tabetics) after the first decade of the disease has not been established, but this probably occurs in some persons.

The antibody detected by the treponemal immobilization test once present apparently persists for life. The appearance of this antibody can be prevented however by appropriate treatment very early in the course of syphilitic infection.

#### CLINICAL PICTURE OF SYPHILIS

**Acquired Syphilis of Adults.** *Early Syphilis (Infectious or Early Latent).* Infectious syphilis is the generalized form of the disease in which one or more lesions rich in *T. pallidum* are present on the exterior of the body. The lesions may appear at any time from a week to several years after onset of infection. In an appreciable number of instances (females 50 per cent, males 30 per cent) the lesions either fail to appear at any time or remain unrecognized by the infected person. Infectious lesions vary in character and extent from a solitary primary or metastatic lesion to a generalized involvement of the skin and mucous membranes. The initial or primary lesion serves as an historic landmark of the portal of entry of the infection but is otherwise intrinsically the same as the metastatic lesions. Even the value of the primary lesion as a landmark is modified by the fact that solitary metastatic lesions occur and may be erroneously identified as primary. Frequently when the patient is first observed by the physician both primary and metastatic lesions are present.

**SYMPTOMS OF INFECTIOUS SYPHILIS.** A unique feature of the early syphilitic infection is the fact that it usually produces virtually no symptoms of systemic disease despite the presence of spirochetemia and widespread metastatic lesions. A possible exception is headache which may occur as a manifestation of the generalization of the infection but more often is a reflection of metastatic involvement of the central nervous system or skull. Fever occurs only

rarely and seldom rises higher than 100.2° F (38° C). The urine is normal. There is no anemia or leukocytosis of the peripheral blood.

Because of the virtual absence of systemic symptoms the patient with syphilis may not seek medical care during the period of infectiousness unless local lesions give rise to symptoms or awaken a suspicion of disease. Thus the physician is usually faced with the problem of identifying a serious generalized infection from a clinical manifestation which appears to be purely local and trivial in nature.

The initial lesion (primary chancre) may appear at any time between the tenth and the ninetieth day after infection but usually is evident within two or three weeks. There is nothing fundamentally characteristic about the appearance of a chancre. The diagnosis can be established only by the demonstration of the presence of the organisms in the lesion even though the syphilitic etiology may be suspected from clinical examination. Because of the subacute nature of the inflammatory process with the extensive occlusion of small vessels the chancre tends to be indurated, circumscribed, relatively avascular and painless. Any or all of these characteristics may be so modified by the location of the lesion and the presence of other infectious processes that no typical picture is consistently produced.

As would be anticipated from the epidemiology of syphilis the initial lesion usually occurs on the skin or mucous membranes of the genitalia, the perianal region, the lips or the oral cavity. Less frequently the finger or the female breast is the site of implantation of the organisms. An ulcerative lesion of these or other areas particularly one which persists for several weeks may represent the initial lesion of syphilis and can be identified as such only by the proper use and interpretation of laboratory examinations.

Regardless of the site of infection the appearance of the chancre is usually accompanied by a moderate enlargement of the regional lymph nodes. The nodes are firm, discrete, movable and are not usually tender. Syphilitic infection does not lead to suppuration of lymph nodes but occasionally a purulent process may develop in inguinal nodes which are involved simultaneously by syphilis and another infection.

On the genitalia multiple infectious lesions of syphilis are common, particularly in the female. In the latter instance the

found convenient therefore to subdivide the term *latent syphilis* into early or late at a point four years after the onset of infection. The line of division is arbitrary and is based on the assumption true in virtually all instances that after four years the reappearance of the generalized stage of the infection is no longer to be anticipated.

*Early latent syphilis* thus may return to the metastatic or infectious variety. Once the focalization of the process becomes stabilized the disease enters into the stage either of *asymptomatic neurosyphilis* or of *late latent syphilis*.

*Late Latent Syphilis* After the stage of late latency has been reached the infection may pursue any one of three possible courses. (1) The foci still present after resolution of the infectious lesions may heal slowly over a period of years with complete eradication of the infecting organisms (biological cure). The incidence of this phenomenon is not known but it probably occurs in approximately 25 per cent of those infected. (2) The foci of infection may persist throughout the life of the host but evoke such a minimal or fortuitously located tissue reaction that the health of the infected person is unimpaired. This course which is analogous to the healthy carrier state in other infections undoubtedly occurs with frequency. (3) The foci may progress at a slow and inconstant rate until sufficient tissue reaction has occurred to produce clinical evidences of disease. This occurs in approximately 15 per cent of the persons with late latent syphilis. The resulting clinical disease may be fatal or benign depending upon the amount of damage and the importance of the structure affected. Although there is virtually no prospect that a person with late latent syphilis (cerebrospinal fluid normal) will subsequently develop neurosyphilis, the person with neurosyphilis may eventually develop clinically demonstrable lesions in other areas of the body in the same manner as occurs in late latent syphilis.

**Location and Character of the Lesions of Late Syphilis** Syphilis may attack virtually any organ or tissue of the body. In the past this fact has been grossly overemphasized for almost without exception serious or fatal syphilis in adults is limited to involvement of the aorta, the central nervous system or the eye. Less frequently the infection becomes evident as the localized single or multiple granulomas which are designated as gummas. The fundamental histopathological lesion of the late forms of

syphilis is essentially the same as that of the early lesions and consists of vascular and perivascular cellular infiltration associated with tissue necrosis and ultimate fibrosis. The chief features which distinguish early from late lesions are that in the latter the amount of necrosis is greater and the cellular reaction less intense. Moreover the treponemes are present in the late lesions only in small numbers and are difficult to demonstrate. Gummas increase in size at an inconstant rate and the destruction of tissue is accompanied by partial healing and fibrosis.

**Prenatal Syphilis** The lesions of prenatal syphilis resemble in general the lesions of acquired syphilis of comparable duration. However in infants who fail to survive for more than a few weeks (or in stillborn infants) the syphilitic process is unusually acute and is characterized by massive spirochetal invasion of all tissues including the lung (*pneumonia alba*). Aortic syphilis which is so common in the infection acquired by adults occurs only rarely in those who survive a prenatal infection.

**Serological Response to Syphilitic Infection** Shortly after infection with *T. pallidum* two distinct antibodies become detectable in the serum of the host. One of these designated *syphilis reagin* exists in close association with the gamma globulin fraction of the plasma, the other known as *treponemal immobilizing antibody* (TPI) can be detected by an *in vitro* test originated by Nelson.

Only the first named antibody *syphilis reagin* can be detected by the various serological tests for syphilis (hereinafter designated STS). As with serological tests in other infections the amount of syphilis reagin present in a specimen of serum can be crudely quantitated by repetition of the test with serial dilutions of the unknown serum. The highest dilution of serum which contains detectable reagin is designated as the titer of the reaction.

The interval between the onset of infection and the appearance of detectable reagin in the serum is dependent upon the sensitivity of the technique employed and varies among individual infections. Usually the STS becomes positive between the third and the sixth weeks after the disease has been contracted. In a minority of instances however the process requires more time and the serological tests may not become positive until approximately three months after the onset of infection. With modern techniques the STS is invariably positive when the dissemination of the in-

fection has become sufficiently intense to result in metastatic lesions in the skin and mucosa

Less precise knowledge is available concerning the length of time during which detectable reagin will persist in the serum of persons who receive no treatment. It is probable that the serological tests for syphilis once positive do not spontaneously revert to negative for at least ten years. Whether spontaneous serological reversal occurs in a significant number of patients (exclusive of tabetics) after the first decade of the disease has not been established but this probably occurs in some persons.

The antibody detected by the treponemal immobilization test once present apparently persists for life. The appearance of this antibody can be prevented however by appropriate treatment very early in the course of syphilitic infection.

#### CLINICAL PICTURE OF SYPHILIS

**Acquired Syphilis of Adults Early Syphilis (Infectious or Early Latent)** Infectious syphilis is the generalized form of the disease in which one or more lesions rich in *T. pallidum* are present on the exterior of the body. The lesions may appear at any time from a week to several years after onset of infection. In an appreciable number of instances (females 50 per cent, males 30 per cent) the lesions either fail to appear at any time or remain unrecognized by the infected person. Infectious lesions vary in character and extent from a solitary primary or metastatic lesion to a generalized involvement of the skin and mucous membranes. The initial or primary lesion serves as an historic landmark of the portal of entry of the infection but is otherwise intrinsically the same as the metastatic lesions. Even the value of the primary lesion as a landmark is modified by the fact that solitary metastatic lesions occur and may be erroneously identified as primary. Frequently when the patient is first observed by the physician both primary and metastatic lesions are present.

**SYMPTOMS OF INFECTION** SYPHILIS. A unique feature of the early syphilitic infection is the fact that it usually produces virtually no symptoms of systemic disease despite the presence of spirochetemia and widespread metastatic lesions. A possible exception is headache which may occur as a manifestation of the generalization of the infection but more often is a reflection of metastatic involvement of the central nervous system or skull. Fever occurs only

rarely and seldom rises higher than 100.2° F (38° C). The urine is normal. There is no anemia or leukocytosis of the peripheral blood.

Because of the virtual absence of systemic symptoms the patient with syphilis may not seek medical care during the period of infectiousness unless local lesions give rise to symptoms or awaken a suspicion of disease. Thus the physician is usually faced with the problem of identifying a serious generalized infection from a clinical manifestation which appears to be purely local and trivial in nature.

The initial lesion (primary chancre) may appear at any time between the tenth and the ninetieth day after infection but usually is evident within two or three weeks. There is nothing fundamentally characteristic about the appearance of a chancre. The diagnosis can be established only by the demonstration of the presence of the organisms in the lesion even though the syphilitic etiology may be suspected from clinical examination. Because of the subacute nature of the inflammatory process with the extensive occlusion of small vessels the chancre tends to be indurated, circumscribed, relatively avascular and painless. Any or all of these characteristics may be so modified by the location of the lesion and the presence of other infectious processes that no typical picture is consistently produced.

As would be anticipated from the epidemiology of syphilis the initial lesion usually occurs on the skin or mucous membranes of the genitalia, the perianal region, the lips or the oral cavity. Less frequently the finger or the female breast is the site of implantation of the organisms. An ulcerative lesion of these or other areas particularly one which persists for several weeks may represent the initial lesion of syphilis and can be identified as such only by the proper use and interpretation of laboratory examinations.

Regardless of the site of infection the appearance of the chancre is usually accompanied by a moderate enlargement of the regional lymph nodes. The nodes are firm, discrete, movable and are not usually tender. Syphilitic infection does not lead to suppuration of lymph nodes but occasionally a purulent process may develop in inguinal nodes which are involved simultaneously by syphilis and another infection.

On the genitalia multiple infectious lesions of syphilis are common, particularly in the female. In the latter instance the

FIG 37 Infectious syphilis metastatic cutaneous lesions

FIG 38 Late syphilis cutaneous gumma of elbow before treatment

lesions are usually metastatic. In the male multiple chancres of the penis are by no means rare.

The primary lesion of syphilis is frequently but by no means invariably accompanied or followed by the development of metastatic lesions of the skin and mucous membranes. Regardless of whether secondary lesions occur the initial lesion slowly heals usually in a two to six week period and may or may not leave a thin atrophic scar. The regional lymphadenopathy subsides less rapidly and may be present in some degree for several or more months. The generalized enlargement of the lymph nodes may resolve or may persist and become more prominent if widespread metastatic lesions develop.

#### Metastatic Lesions (Secondary Syphilis)

The visible manifestations of the generalization of the syphilitic infection are encountered chiefly in the skin and mucous membranes. The surface involvement varies in extent from one or several lesions in a single area to widespread involvement of skin and mucosa. Although the cutaneous and mucosal lesions frequently coexist it is important to realize that they may occur independently of each other. The character of the cutaneous lesions is protean. With the exception of a vesicular eruption which is never produced by acquired syphilis virtually any type of rash may develop. The forms which are most frequently encountered are a faint red macule (1 to 3

mm in diameter) a reddish brown papule or a folliculopapule. Although the pigmentation of the papule is presumably caused by the extravasation of blood the process never becomes sufficiently acute to give rise to hemorrhagic lesions. Less frequently the infection produces an annulopapular pustular eruption (ulcerated) or psoriasiform eruption. The annulopapular pustular and folliculopapular varieties are encountered more frequently in Negroes.

The distribution of the cutaneous lesions may be of more value than the morphology in directing the suspicion of the clinician toward the possibility of the presence of syphilis. As the infection is blood borne the lesions are generalized and may develop on the palms, soles and face in addition to or independently of involvement of the skin of the trunk and extremities. In infections other than syphilis (meningococcemia, staphylococcemia, the rickettsial and viral diseases) in which skin lesions appear in the characteristic blood borne distribution the patient usually presents obvious evidence of acute systemic disease. Syphilitic lesions of the palms or soles usually appear as dark reddish brown macules or papules. Occasionally on the hands and feet the infection may produce a superficial scaling eruption which simulates a fungal infection.

**INVOLVEMENT OF MUCOUS MEMBRANES**  
Metastatic (secondary) syphilitic involvement of the mucous membranes may ap-

pear as a simple erosion a papulo-erosion or as a hypertrophic papular or symmetrically spread lesion which is designated by the term *condyloma latum*\* The simple erosive and papulo-erosive lesions occur in the buccal mucosa or on the genitalia The erosion is usually covered by a thin silvery gray membrane (*mucous patch*) and is surrounded by little inflammatory reaction Multiple lesions are common particularly in the oral cavity The erosions do not usually produce any symptoms unless they are located on the tonsillar pillar or tonsil where they may cause moderately severe symptoms of tonsillitis or pharyngitis

*Condyloma latum* occurs most frequently in moist areas such as the lips the female genitalia and in the perianal region of both sexes On the labia majora the lesions are usually multiple and consist of flat raised nodules which are approximately a centimeter in diameter In the other areas particularly around the anal orifice the condyloma may appear as an indurated slightly raised purple brown lesion which extends symmetrically over the surrounding skin for an area of 2 or 3 cm Unless traumatized or secondarily infected condylomas are not usually ulcerated A perianal condyloma like any lesion close to the anal sphincter may cause considerable pain on defecation In the presence of this symptom the highly infectious condyloma is frequently mistakenly identified as a "fissure" or a "thrombosed hemorrhoid"

A mucocutaneous lesion of syphilis which is deserving of special mention is the so-called "split papule" The lesion consists of a tiny moist papule which develops at the angle of the mouth where it becomes split in one or more places A papule in this location may represent the sole demonstrable lesion of a syphilitic infection yet may easily be overlooked because of the frequent occurrences of innocuous traumatic fissures at the corners of the mouth

**INFECTIVITY OF CUTANEOUS AND MUCOSAL LESIONS** All of the cutaneous and mucosal lesions of early syphilis contain *T pallidum* in considerable numbers and hence are potentially infectious for others The most dangerous lesions from the standpoint of transmissibility are the innocuous appearing ulcerated lesions about the lips or in the mouth

**EARLY NEUROSYPHILIS** Involvement of the central nervous system during the

course of infectious syphilis is demonstrable in an appreciable number of patients by examination of the cerebrospinal fluid Usually this inflammatory process is not sufficiently intense to produce symptoms other than a mild or moderately severe headache Occasionally however the presence of the infection in the central nervous system becomes clinically evident This early symptomatic neurosyphilis is an extremely rare occurrence among patients with untreated infectious syphilis but develops not infrequently in patients who have received subcurative therapy The presenting clinical picture of early symptomatic neurosyphilis is characterized by evidence of disease of the meninges or of the arteries of the brain and is discussed in a subsequent chapter

**OTHER METASTATIC LESIONS OF EARLY SYPHILIS** The metastatic lesions of early syphilis which may occur in addition to those already described are a generalized enlargement of lymph nodes only rarely accompanied by splenic enlargement alopecia of an irregular moth-eaten type distinct from the completely hairless areas of alopecia areata and three types of ocular disease *iritis neuritis* or *retinitis* For a detailed presentation of the ocular involvements which may occur during the course of infectious syphilis the authoritative review of Woods should be consulted

It is reasonable to assume that the development of metastatic lesions during the course of infectious syphilis is not limited to those structures in which the presence of infection is so easily demonstrated Nevertheless the development of clinically detectable disease of other organs or structures is remarkably infrequent

**Diagnosis of Infectious Syphilis** No matter how experienced the clinician or how characteristic the lesions the diagnosis of infectious syphilis cannot be established with certainty except by darkfield microscopy Less certain but generally acceptable evidence of the presence of the infectious state is the finding of consistently positive STS in a patient who presents lesions which have the appearance of syphilis and which respond promptly to anti-syphilitic therapy Although patients who present this combination of findings are usually syphilitic there is no proof that the infection is recent and the presumed infectious lesions may represent manifestations of a coincidental disease Despite the fact that the proof of the diagnosis of infectious syphilis rests entirely on laboratory procedures it is essential that the physician be alert for possible clinical evidences of syph

\* Not to be confused with *condyloma acuminatum* the venereal or genital wart which has the characteristic appearance of warts occurring elsewhere

ilis in order that the laboratory tests may be properly employed

The finding of a genital lesion no matter how nondescript or apparently benign should immediately arouse a suspicion of syphilis. The possibility of syphilis should also be suggested by the presence of a lesion particularly one which persists for several weeks anywhere on the body. Moreover a cutaneous eruption of blood borne distribution in a patient who shows no evidence of acute systemic infection is highly suggestive of infectious syphilis. In the presence of these frank manifestations of syphilitic infection the physician is usually prompt in obtaining the necessary diagnostic laboratory tests. In an impressive number of instances however the presence of syphilis is by no means so readily apparent. The greatest opportunity for error does not arise from the presence of a genital lesion or a generalized eruption but from the apparently solitary lesions in other areas. The tendency is strong for the physician or the regional specialist to regard a particular abnormality as a localized and trivial disease and to fail to ascertain that similar abnormalities are present in other regions of the body.

**Exclusion of the Presence of Infectious Syphilis.** Not infrequently the physician is confronted by a patient who fears that he has contracted syphilis from a particular exposure and who presents cutaneous or mucosal lesions genital or otherwise in which *T. pallidum* cannot be found. The question immediately arises as to whether the eruption or ulceration is a manifestation of infectious syphilis. In the case of a generalized cutaneous eruption the problem may be solved immediately by the performance of an STS. If the test is negative syphilis can be excluded from consideration for the serological tests attain virtually 100 per cent sensitivity in the presence of a generalized eruption. The problem is not so easily solved if the lesion is solitary. The proper procedure is to examine material from the suspected lesion under the darkfield microscope for three successive days and to obtain blood for serological testing. If no spirochetes are found and the lesion heals STS should be obtained at four or five day intervals during the first two weeks and at two week intervals thereafter. The serological follow up should be continued for ninety days after the suspected exposure or after the appearance of the lesion if multiple exposures had previously occurred. The physician should emphasize the fact that the nega-

tive STS obtained during the course of the period of observation do not exclude the presence of early syphilis. To be sure as the follow up continues from week to week the significance of negative tests is steadily increased and the chances that the person is developing syphilis become increasingly remote.

**Early Latent Syphilis.** The term *early latent syphilis* merely designates those patients who fail to present any lesions of infectious syphilis at the time of examination. As mentioned previously the patients with early latent and with overt infectious syphilis present essentially the same problem in management. The diagnosis of early latent syphilis is made from (a) a history of a recent diagnosis of infectious syphilis (b) serological evidence of syphilis in a person with a history suggestive of a recently acquired infection (c) discovery of serological evidence of syphilis in a person known to have been free from infection in the recent past.

#### LATE SYPHILIS

**Late Latent Syphilis.** An understanding of the clinical entity of *late latent syphilis* is essential for approximately 80 per cent of the syphilitic patients seen by the practitioner are in this stage of the disease. Many patients with late latent syphilis are either grossly overtreated or sadly neglected. Once true latency has been established the subsequent course of the infection is usually benign. It is important therefore that this relatively benign and frequently encountered form of syphilis be clearly distinguished from the potentially serious types of infection which may require different therapy.

As defined previously *late latent syphilis* is the term which designates those patients with serological or historical evidence of syphilis of more than four years duration but in whom no evidence of syphilitic disease is detectable by (a) complete physical and neurological examination (b) an examination of the cerebrospinal fluid (c) roentgenographic examination of the heart and aorta.

Unless these criteria are met it is possible to overlook detectable and potentially serious syphilitic infection. Therefore the physician should obtain the information made available by these three procedures as quickly as possible. Although the problem of establishing the latency of a syphilitic infection presents no difficulties it may be difficult to prove that the infection is of more than four years in duration. Fre-

quently the patient will relate a history of the previous discovery of a positive serological test or of some lesion which was diagnosed and treated as syphilis. In the absence of such a history the physician must exercise his own judgment as to whether the undoubtedly latent infection is recent or old. As with other chronic infections such as tuberculosis it is advisable to regard syphilis of unknown duration in a young person as a recently acquired infection.

**Syphilis of the Cardiovascular and Central Nervous Systems** Virtually all of the fatalities from syphilis arise from involvement of either the cardiovascular or central nervous systems. It is not generally appreciated that aortic and neurosyphilis frequently occur together. These two most serious forms of syphilis are discussed in following chapters.

**Ocular Involvement in Late Syphilis** The most frequently encountered and serious forms of ocular syphilis, optic neuritis, optic atrophy and interstitial keratitis are discussed below and in the chapter on Neurosyphilis. In addition, iritis, chorioretinitis and rarely a gumma of the orbit or eye may develop as late manifestations of the infection. Both iritis and chorioretinitis occur in association with many diseases other than syphilis, and the syphilitic form of these ophthalmic disorders is in no way distinctive.

**Gummas** Although the development of a gumma has been observed at one time or another in virtually every organ of the body, these focal lesions of late syphilis seldom occur in tissues other than those of the skin, bones, liver, testes or larynx. It must be appreciated that it is not usually possible to establish with certainty that a particular lesion is a gumma either by the examination of biopsy specimens or by the demonstration of *T. pallidum* in the affected tissue. *T. pallidum* is notoriously difficult to demonstrate in most lesions of late syphilis, and the histopathological picture of a gumma, while characteristic of syphilis, may also be simulated by a number of other chronic granulomas. From the standpoint of diagnosis, therefore, a gumma is a chronic granulomatous lesion reasonably characteristic in appearance which develops in a person with syphilis and which resolves with residual fibrosis within a few weeks of the institution of antisyphilitic therapy. The results of the STS are of great value in the diagnosis of a gumma; with modern techniques the tests are al-

most invariably positive in high titer. Conversely, the finding of a negative STS (with no history of previous antisyphilitic therapy) constitutes strong evidence against the possibility that a particular granuloma is syphilitic in origin.

**Skin** In contrast to the multiple lesions of the skin which may appear during the course of infectious syphilis, cutaneous gummas are usually localized to a single area. The skin of the face, neck and extremities is most frequently involved, presumably because of the influence of trauma. The lesion arises in or under the skin as a nodule which enlarges at so slow a rate that it produces no pain or tenderness. The nodule may eventually break down, forming a symmetrically rounded ulceration with an indurated base which is covered with a small amount of exudate. Although the individual intact nodules are reddish brown, there is a gray blue coloration along the periphery of the gumma, which is sufficiently characteristic to be helpful in diagnosis. The ulcerated or indurated lesions heal slowly and are replaced by a thin, smooth scar which retains the configuration of the active process and is surrounded by a pigmented border. If untreated, a cutaneous gumma may persist in varying stages of activity for a period of months or even for several years. Gummas of the skin may simulate a number of diseases and are frequently mistaken for various ulcers of the legs or for lupus erythematosus (discoid type) of the face.

**Juxta-articular nodules** are firm subcutaneous gummas which may develop on the extensor aspects of the elbows or knees, close to the insertion of the muscle. The nodules seldom enlarge to more than 1 or 2 cm in diameter and rarely ulcerate.

**Skeletal System** Gummatous lesions of the skeletal system develop in approximately 5 to 10 per cent of patients with late syphilis, more commonly in Negroes than in whites. The process may involve the periosteum, the cortex or the medullary cavity. The periostitis is primarily proliferative but in osteitis and osteomyelitis both destructive and proliferative processes are present together. In syphilitic involvement of the skull the lesions are predominantly destructive in character.

Syphilitic disease of bone is often mistaken for sarcoma, tuberculosis or metastatic carcinoma. Gummas may be differentiated from these other diseases by (a) the STS, which is almost invariably positive in high titer in the presence of syphilis.

of bone (b) the appearance of the lesion in the roentgenogram (c) biopsy and (d) the response to antisymphilitic therapy

The finding of a negative STS constitutes strong evidence against the diagnosis of osseous syphilis. Moreover, it is essential to realize that if a suspected lesion is an active gumma, it will show evidence of healing within a few weeks of the institution of therapy. Unless definite symptomatic improvement appears within a four week period, therapeutic trial should be discontinued and a biopsy performed because of the possibility of neoplastic disease.

*Syphilis of the Liver* Syphilis is a rare cause of clinically detectable disease of the liver and is discussed in the chapter on Diseases of the Liver.

*Gumma of the larynx* develops occasionally in persons with late syphilis. The chief clinical manifestation of this form of syphilis is the development of severe and persistent hoarseness in a person who is otherwise completely asymptomatic. Gummas may closely simulate tuberculous or neoplastic disease of the larynx. Therefore a therapeutic test should not be attempted until an effort has been made to exclude the presence of these more serious diseases.

*Gumma of the testicle or epididymis* occurs rarely and is characterized by the development of a firm, smooth, occasionally nodular mass which slowly enlarges in size. Testicular gummas seldom produce symptoms other than a dragging sensation caused by the weight of the mass. As neoplasms arising from the testicle may grow and metastasize with great rapidity, the physician must be unusually wary in order to avoid the serious error of performing a therapeutic test for syphilis in a patient with a malignant neoplasm.

*Gummatous Formation on Other Structures* As mentioned previously, the development of the localized gummatous lesion of late syphilis has been observed in virtually every tissue of the body. Because of the rarity with which gummas appear in structures other than those noted above, no attempt will be made to catalogue all the possible sites of involvement. Nevertheless, certain points should be emphasized.

Gummas usually produce clinical manifestations similar to those caused by chronic infectious or neoplastic disease of a particular structure. Therefore, even in a patient known to have syphilis, the physician should be slow to accept the diagnosis of gumma in a site of infrequent involvement until the possibility of neoplasm has been excluded (by biopsy or surgical exploration

if necessary). Moreover, even in patients who have been infected with syphilis, the presence of a gumma is distinctly unlikely if the STS is negative.

#### SYPHILIS IN PREGNANCY

A woman infected with syphilis can transmit the disease to a fetus for an undetermined period of years after she has contracted the infection. As would be anticipated, the chance of intrauterine transmission of syphilis is greatest when the infection has been recently acquired and diminishes throughout successive pregnancies. Infection of the fetus usually occurs after the fifth month of pregnancy and may result in spontaneous abortion, miscarriage, a stillborn fetus, or a fatally ill infant.

*Prenatal Syphilis* The clinical manifestations, course, and diagnostic problems presented by syphilitic infection in infancy and early childhood are beyond the scope of the present article. The clinical manifestations and the course of prenatally acquired syphilis in adults are, with few exceptions, essentially the same as in acquired infections of comparable duration. The unique features of the prenatal variety are the frequency of *interstitial keratitis* and the virtual absence of aortic involvement. Ophthalmological texts should be consulted for a discussion of interstitial keratitis. Localized gummatous lesions occur in prenatally acquired syphilis and are identical in every respect with the gummas of late syphilis acquired in adult life. Skeletal involvement is not uncommon and in the form of osteitis or periostitis may produce saddle nose or sabre shins. A nongummatous form of skeletal involvement which is unique to prenatally acquired syphilis is the characteristic malformation of the teeth described originally by Hutchinson. The changes are most conspicuous in the central incisors, which are unusually small, widely spaced, notched, and less broad at the cutting edge than at the gum margin. A rarely encountered syndrome of Hutchinsonian teeth, *interstitial keratitis*, and *eighth nerve deafness* (caused by meningeal involvement) is known as *Hutchinson's triad* and is considered to be unequivocal evidence of the presence of prenatal syphilis.

*Pregnancy* Adult women with prenatally acquired syphilis may transmit the infection to their offspring during pregnancy. Such third generation syphilis is extremely rare but seemingly indisputable instances of its occurrence have been reported. More often an apparent instance

of this phenomenon is the result of syphilitic infections contracted independently by a mother and her daughter and the subsequent intrauterine transmission of the disease by the latter

### SEROLOGICAL DIAGNOSIS OF SYPHILIS

The serological tests for the presence of syphilis reagin (STS) assume a greater or lesser importance in diagnosis depending upon the type of syphilitic infection which is under consideration. In infectious syphilis the serological tests are distinctly secondary in importance to the demonstration of *T pallidum* by darkfield microscopy. In certain varieties of cardiovascular and neurosyphilis the serologic tests are chiefly of value as an additional confirmation of the clinical diagnosis. In the great bulk of infections observed by the practitioner however the diagnosis of syphilis can be established only by serological testing. It is essential therefore that an STS be obtained as part of the routine of the initial examination of every patient. It is equally important that the results of such tests be subjected to proper interpretation.

The Wassermann test and the other tests designated by proper names are all based on the same immunological phenomena and all detect the same substance *syphilis reagin*. In a very real sense all of these tests are nonspecific. This fact presents no difficulties when the STS is employed to confirm a diagnosis of syphilis made by clinical examination or from the patient's history. The nonspecificity becomes of the greatest importance however when a positive STS represents the sole indication that a patient might have syphilis. For in addition to syphilis and the other treponemal infections (yaws, pinta, bejel) there are other states not necessarily infectious which may give rise on occasion to a positive STS. Such results of serological testing are designated *biological false positive reactions* or BFP. The incidence of these reactions has not yet been defined but it has been credibly estimated (Moore) that in certain highly selected populations in the US the incidence may approach 50 per cent.

The finding of a positive STS in a person with absolutely no clinical or historical evidence of syphilis is thus to be regarded as a highly significant lead but it does not necessarily establish the presence of syphilis.

Situations in which it is well for the physician to be particularly wary of the diagnosis of syphilis solely on serological evidence are: (a) the presence of a posi-

tive STS in a patient who is suffering or convalescing from an acute infection (b) the finding of a positive STS in a patient who has had a recent negative test and whose sexual partners are nonsyphilitic and (c) the finding of a series of doubtful (i.e. "one to three plus") STS possibly punctuated by an occasional positive in a person who credibly denies having experienced any previous manifestations of syphilis or antisyphilitic therapy.

The problem of the person with the recent acute infection is relatively simple as the false positive STS which occurs in this setting are usually transient. The treponemal immobilization reaction of Nelson can be of immense help and it is current practice to regard all STS reactors whose serum is negative by the immobilization test as being truly nonsyphilitic. Unfortunately however relatively few laboratories are presently able to perform the treponemal immobilization test on a service basis. Hence in most circumstances the problem must be managed by the exercise of arbitrary judgment.

Accordingly whenever the standard STS are repeatedly positive in a person with no clinical or historical evidence of syphilis or the other states mentioned above it is advisable to treat the patient as if early latent syphilis were present (see below). For a detailed discussion of this question of the significance of serological tests for syphilis the reader should consult the reports by Moore and Mohr and by Davis.

### TREATMENT

**Early Syphilis.** The goal of antimicrobial therapy in syphilis is to effect a drastic reduction of the population of *T pallidum* to a census readily manageable by the host. In early syphilis (infectious and early latent) attainment of this goal by penicillin is followed in 85 to 90 per cent of infected persons by an apparently complete disappearance of *T pallidum* from the body. In the remainder after disappearance of the acute manifestations the infection survives into the late latent stage or reappears as an infectious or neurological relapse. The possibility of such relapse can be minimized by continuation of the antimicrobial therapy for a matter of months. In such circumstances it is highly unlikely that the continued therapy *per se* eradicates the persisting *T pallidum*. On the contrary eradication during prolonged therapy is presumably accomplished either by the defenses of the host or more probably by

the natural death of the parasites after their prolonged physiological confinement

As the incidence of relapse after short term therapy is so relatively low it seems impracticable and indeed inadvisable to subject all patients with early syphilis to the months of treatment necessary for only a few. Accordingly an acceptable procedure is to treat all patients with early syphilis with only a single large dose of one of the long lasting preparations of penicillin.

A satisfactory regimen for this purpose consists of the intramuscular injection at multiple sites of a total dose of 2 400 000 units of one of the long lasting penicillins. The entire dose may be administered at one visit or may be divided over two successive days. The most satisfactory preparation is *benzathine penicillin G* fortified with *procaine penicillin G* which is available under a variety of proprietary names. Procaine penicillin in oil containing 2 per cent aluminum monostearate can be substituted in the same dosage.

In the relatively remote event that relapse or other failure of treatment should be detected on subsequent observation the patient could either be retreated with the above described regimen or could be given 900 000 units of procaine penicillin per day on eight successive days excluding Sundays. In situations in which it is desired to reduce the chance of relapse to a minimum it is advisable to prolong therapy for a six month period by the addition of 300 000 units of procaine penicillin once or twice weekly to either of the two short term regimens.

A number of other drugs notably chloramphenicol and the tetracyclines are relatively imperfect substitutes for penicillin in the treatment of syphilis. Regimens for the use of these other drugs have not been clearly defined. Hence when penicillin can not be used it would seem advisable to administer chloramphenicol or a tetracycline drug orally for a two week period in a total daily dose of 3.0 gm. with unusually meticulous clinical and serological follow up observations thereafter.

**Course of Early Syphilis Under Treatment** In early syphilis an acute exacerbation of any visible lesions may become evident within six to ten hours of the initiation of treatment. This exacerbation soon after the institution of antimicrobial therapy is designated the *Herxheimer reaction* and occurs to some degree in the majority of patients with early syphilis. It is seldom sufficiently emphasized that the intensity of a Herxheimer reaction reflects the in-

tensity of the syphilitic inflammation before treatment. Thus lesions which are poor in *T. pallidum* are less likely to develop an acute exacerbation following the start of therapy than the infectious lesions of early syphilis. The duration of the reaction is short (two to four hours) and in early syphilis the phenomenon is in no way harmful.

The rate of disappearance of *T. pallidum* and the healing of the external lesions are modified by their number and size. In general within twenty four hours of the start of therapy *T. pallidum* is no longer demonstrable in the lesions and the latter show evidence of the onset of resolution. During the succeeding week healing proceeds rapidly. All but the most unusually extensive processes are completely healed save for residual pigmentation or scarring within seven to ten days after the start of therapy.

At this point the patient presents little or no clinical evidence of syphilitic infection but unless treatment was started before the development of seropositivity the serological tests are still positive.

During the first six months after the start of treatment the patient should be seen at intervals of two weeks and questioned for symptoms suggestive of mucocutaneous, ocular or neurological relapse. Moreover the questioning should be supplemented by a complete examination of the skin, oral cavity, genital and perianal regions, superficial lymph nodes, anterior eye and fundus, cranial nerves and the tendon reflexes of the extremities. Material from a lesion which makes its appearance should be examined by darkfield microscopy. At the same two week interval a specimen of blood should be obtained for serological testing. When facilities are available the blood specimens obtained before, during and after treatment should be tested in serial dilution if the usual qualitative test is positive (i.e. four plus). A pronounced fall in titer (e.g. positive when diluted 1 to 128 changed to positive when diluted 1 to 4 and negative on further dilution) may be detectable at a time when the usual qualitative test would be reported simply as positive (i.e. four plus). Even with the aid of quantitative tests a change in the STS may not become evident until the third or fourth month after the start of treatment. Between the third and sixth month after the institution of therapy the serological reactions gradually become negative in the majority (approximately 80 per cent) of treated cases. In a small number of patients (5 or 10 per cent) the

reaction may not be consistently negative at six months but the titer will have fallen considerably and the reaction will become completely negative by the ninth or twelfth month after the start of treatment. In the remaining group of infected persons (5 or 10 per cent) despite some fall in titer during and after treatment the serological tests for syphilis will be repeatedly positive (i.e. four plus) one year after the institution of therapy. Some of this latter group may attain seronegativity during the second post treatment year.

In a small proportion of treated infections persistently positive serological reactions may show a steady increase in titer or the reaction once negative will again become positive. In evaluating such sero relapse it is essential that the physician realize that minor fluctuations below the range of complete positivity (i.e. so-called "one plus to three plus reactions") are merely a reflection of the day-to-day variation in the sensitivity of the serological test in the laboratory and have no significance in respect to a change in the serologic status of the patient. Only a change from complete negativity to complete positivity or a two fold change in titer can be considered as definite evidence of serological relapse. Although clinical relapse does not invariably accompany or follow serological relapse a correlation between the two phenomena is so frequent that they have an identical significance in terms of therapy.

A satisfactory serological response to treatment in early syphilis may thus be defined as complete or virtually complete seronegativity six months after treatment was started. It is probable that many persons who fail to show such prompt serological reversal require no further therapy. In the present state of knowledge however it is advisable to regard all such cases as therapeutic failures and to reinstitute therapy.

Six months after the start of therapy it is essential to determine the total cell count, total protein, colloidal gold and STS of the cerebrospinal fluid. In the event that abnormalities are present treatment for early neurosyphilis should be instituted according to the principles discussed in a following chapter. If the cerebrospinal fluid is normal at this time it is necessary to examine it on one more occasion after an interval of one year i.e. eighteen months after therapy.

If at six months after the start of therapy for early syphilis the patient presents no evidence of relapse on clinical or cerebro

spinal fluid examination and the blood serological tests have shown a satisfactory response the interval between examinations (clinical and serological) may be extended to one month. The procedure at the time of each visit should be exactly the same as when the patient was examined at fortnightly intervals and the monthly examination should be continued for one year. The clinical and serological follow up should be continued for a total period of five years but the interval between examinations may be gradually lengthened to three to six months after the first eighteen months of observation have been completed.

**Prognosis of Early Syphilis Following Penicillin Treatment.** The incidence of either biological cure (i.e. complete eradication of *T. pallidum*) or of permanent latency which may be expected following the use of present-day methods for the penicillin treatment of early syphilis cannot yet be stated with precision. In broad terms it can be said that biological cure is apparently attained in 85 to 90 per cent of the persons who receive one course of treatment and in a substantial proportion of those who require retreatment. The ultimate outcome of the infection among patients with apparent biological cure two or three years after treatment is almost uniformly excellent. A few patients with early syphilis will fail to become serologically negative. If they have been adequately treated including a second course of penicillin treatment for the seroresistance and have no evidence of syphilis other than a low titer on quantitative serological test they may be safely followed without further treatment.

**Relapse and Reinfection in Early Syphilis.** Post treatment relapse of early syphilis is a phenomenon which if unrecognized has serious implications. The incidence of complicating lesions in the eye or nervous system appears to be appreciably higher in the case of post therapy relapsing infections than in the course of relapsing untreated syphilis. Moreover opportunity for transmission of the infection is enhanced as the person may not appreciate that the cutaneous or mucosal lesions of relapse are related to the treated venereal infection of several months previously.

Reinfection probably accounts for a considerable number of the treatment failures. The patient is cured of his infection before he has mobilized resistance to *T. pallidum* and hence can become reinfected. With the old long term arsenical and bismuth ther-

apy the patient was protected from reinfection while he was under treatment and presumably also had developed considerable immunity by the time therapy was completed

**Late Latent Syphilis** It is probable that once true latency (*vide supra*) has been established there is no need for the administration of antisyphilitic therapy. Moreover the possibility exists that the organisms which persist within the host after the development of true latency are not particularly susceptible to antimicrobial therapy. Unfortunately there is no way by which apparently latent syphilis can be distinguished from active disease of the aorta or other viscera which has not progressed to the point of clinical recognition. Thus the physician has no choice other than to treat all persons with late latent syphilis.

From the preliminary experience in the treatment of early syphilis with penicillin and from the available knowledge of the course of the infection once late latency has been established it would seem that regimens which constituted adequate therapy for early syphilis would be at least equally effective in the treatment of late latent syphilis. Because the problem with late latent syphilis is less urgent however it is permissible to use a regimen of 600 000 units of procaine penicillin administered twice weekly for a four week period.

**Course Under Therapy and Prognosis** As by definition persons with late latent syphilis exhibit no clinical evidences of infection they will show no change in clinical status as a result of successful therapy. In an individual patient with late latent syphilis a precise evaluation of the result attained by therapy or natural immunity can only be made by following the patient throughout his entire lifetime. Until sufficient time has elapsed to permit a long term evaluation of the results of the penicillin therapy of late latent syphilis therefore the expected outcome of the infection in a person treated with penicillin can only be surmised from the results of penicillin therapy in other forms of syphilis. A reasonable prediction would be that less than 2 per cent of patients with late latent syphilis who are properly treated will subsequently develop a serious manifestation of late syphilis. The few who do exhibit evidence of progression despite theoretically adequate treatment will be chiefly those in the older age groups who had well established but clinically unrecognizable aortitis at the time of the treatment of the apparently latent syphilis.

**Serological Reversal in Late Latent Syphilis** In late syphilis (including the latent variety) the serological tests do not reverse to normal after treatment so readily and uniformly as they do following the therapy of recently acquired infections. This frequent failure of the serological tests to become normal is designated *seroresistance*. There are two important facts concerning seroresistance which must be fully appreciated by the physician. (1) There is no reason to believe that the phenomenon of seroresistance alters the outcome of the treated infection in any way. (2) Seroresistance cannot be influenced by additional therapy. Once it is established that a patient with late latent syphilis has received a proper regimen of therapy it is as irrational to continue therapy because of a persistently positive *STS* as it would be to persist with antituberculous chemotherapy merely because of the continued presence of a positive tuberculin reaction. The physician should realize that the last almost without exception hold the erroneous notion that a positive *STS* signifies the actual presence of *T pallidum* in the particular specimen of blood which was tested. Therefore it is important to explain in understandable terms the true significance of serological tests to each patient who is infected with syphilis. It must be appreciated that seroresistance by definition is the phenomenon observed only in latent syphilitic infections. The persistently positive serological tests in persons with obvious progressive lesions of the aorta or nervous system are not to be considered as examples of seroresistance.

**Examination of the Cerebrospinal Fluid in Late Latent Syphilis** In contrast to the situation which exists in early syphilis the cerebrospinal fluid is examined *before* the institution of therapy in late latent syphilis for a normal fluid is one of the prerequisites for the diagnosis of latency. In the event that a latent infection has been proved to be really late *i.e.* of more than four years duration subsequent examinations of the cerebrospinal fluid are not necessary. In those instances in which it is impossible to determine the duration of the infection and hence the possibility of early latent syphilis cannot be excluded the cerebrospinal fluid should be reexamined eighteen months after the institution of therapy.

**Treatment of Gummas** The penicillin regimens appropriate for late latent or for early syphilis are entirely adequate for the treatment of a gumma. If aortic or neurosyphilis is also present it should receive

precedence in the choice of therapy and a penicillin regimen appropriate for aortic or neurosyphilis would also be appropriate for a gumma. When a gumma is strategically located as in the larynx it is advisable to administer only two 25 000 unit doses of penicillin on the first day of treatment. In this way the intensity of a Herxheimer reaction might be modified even though its occurrence cannot be completely prevented. The complete regimen can then be started on the following day. Within the first week of treatment there will usually be subjective and objective evidence of improvement in the status of the lesion. Resolution of the lesion or lesions is steadily progressive but the time required for complete healing will vary from several weeks to several months depending upon the original size of the gumma. Once the lesions are completely healed the subsequent course and the management of the patients are the same as in late latent syphilis.

**Treatment of Syphilis in Pregnancy.** An ST should be obtained on every pregnant woman during the first and last trimesters of pregnancy and any woman who has had syphilis should be evaluated as to the need for antisyphilitic treatment with each pregnancy. Formerly treatment was repeated with each pregnancy. This is no longer deemed necessary and the present practice is to allow a pregnant woman to reach term untreated provided that she has received theoretically adequate therapy in the past. Shows no clinical evidence of active syphilis and is seronegative.

Early syphilis in the pregnant woman carries the greatest risk of infection of the fetus. Nevertheless with penicillin a normal infant can be expected even if the disease is discovered late in pregnancy. The penicillin regimens recommended for early syphilis are satisfactory for the treatment of syphilis in pregnancy. If the infection is not discovered until after the thirty-second week of pregnancy however it is advisable to administer 300 000 units of procaine penicillin three times daily for at least eight days.

**Treatment of Prenatally Acquired Syphilis.** Except for interstitial keratitis the treatment of the various manifestations of prenatally acquired syphilis which are first recognized during adult life is the same as in the corresponding situations with syphilis contracted during adult life. *Interstitial keratitis* is a potentially serious complication which should be treated promptly and intensively with penicillin and cortisone or

corticotropin. Procaine penicillin 300 000 units intramuscularly should be administered each day for a two week period. Preliminary observations indicate that cortisone and corticotropin systematically are equally effective but apparently no more so than cortisone when used locally. When ever possible interstitial keratitis and the other ocular manifestations of syphilis should be treated in consultation with an ophthalmologist.

#### INDIVIDUAL PROPHYLAXIS AND THE PREVENTION OF SYPHILIS

The most effective prophylaxis against syphilis is the use of a condom during sexual intercourse and a thorough cleansing of the genitalia and adjacent areas with soap and water immediately thereafter. These measures afford an appreciable amount of protection to either sex against the direct genital transmission of the infection. There is no efficacious method of protection against transmission by other bodily contacts. The most practicable method for the prevention of syphilis among a civilian population is to effect a reduction in the prevalence of infectious syphilis by the prompt recognition and proper therapy of all persons with recent infections. In this way the incidence of new contact infections can be sharply reduced.

#### PSYCHOLOGICAL AND SOCIAL ASPECTS OF SYPHILITIC INFECTION

The mechanics of the diagnosis and treatment of syphilis are simple and require but little of the physician's time. Not infrequently however the patient's discovery that he or she has syphilis immediately gives rise to problems which occasion considerable mental distress. Although these problems appear uniquely insolvable to the person concerned they can usually be settled satisfactorily by the physician who is willing to devote the time. It is not sufficient for the physician merely to "answer any questions." Frequently a reticent patient will cherish all manner of unwarranted fears about the effects of the infection on himself or his intimates without betraying such fears to his physician. Therefore at the same visit at which the diagnosis of syphilis is announced it is essential that the physician undertake an active discrediting of the folklore of syphilis and an honest presentation of the facts and potentialities of syphilitic infection. The questions of transmissibility to others the risk of neurosyphilis the chances of

having nonsyphilitic children and the significance and expected course of the serological tests should be discussed in detail. The circumstances under which it would be proper for the patient to marry depend upon the stage of the infection. In general it is not advisable for the patient to marry a nonsyphilitic person until the danger of infectious relapse is minimal i.e. one year after an adequate course of penicillin therapy. An infection of more than four years duration should not constitute a barrier to marriage from the standpoint of transmission of infection to the spouse. The presence of neurosyphilis however constitutes a certain economic liability and in decisions on the advisability of marriage should receive exactly the same consideration as any other physical handicap. Obviously if the physician knows or suspects that a patient has paresis every effort should be made to prevent marriage.

In marital and premarital problems the physician should exert all his influence to have the patient inform spouse or fiancée of the diagnosis of syphilis. Although the

patient (and some physicians) frequently believe that the announcement to the marital partner that the patient has syphilis will 'break up the marriage' such fears are almost invariably unwarranted. In the unusual event that a patient with *potentially infectious* syphilis refuses to inform the marital partner the physician should undertake to do so.

## Nonsyphilitic Treponematoses

For many years it has been recognized that there are a number of disease syndromes occurring principally among the more backward peoples of warm countries that are syphilis like in their general course and symptomatology. These syndromes have both clinical and epidemiological features which still make it useful to give them distinguishing names such as *yaws*, *bejel*, *pinta* and *endemic syphilis*.

It is now known that the etiological agent of each of these disease syndromes is a spiral microorganism which is indistinguishable morphologically from the treponeme of syphilis, *Treponema pallidum*. Moreover infected persons develop serum antibodies—Wassermann antibody and treponemal immobilizing antibody—just as do persons with syphilis. Significant degrees of cross immunity can be demonstrated experimentally and each disease responds well to the usual antisyphilitic drugs such as penicillin and the arsenicals.

On the basis of the foregoing considerations it is becoming common practice to refer to this group of diseases including syphilis as the *treponematoses*. Nevertheless real clinical and biological differences do exist among the various diseases belong-

ing to this general group differences which bear on problems of diagnosis treatment prevention and community control. From a more academic standpoint the relationship of these diseases one to another presents absorbing problems to the medical biologist interested in microbial variation and mutation as influenced by climate race and other ecological factors.

It is clear from clinical epidemiological and laboratory investigations that these are not simply different manifestations of the same disease for each disease will reproduce itself under controlled experimental conditions. Laboratory experiments suggest however that long continued exposure of infected hosts to different environmental conditions eventually results in modification of certain biological characteristics of the particular treponemes. To what extent this same phenomenon may occur in nature is still only a matter for speculation.

Finally to complete and at the same time confuse the picture of this group of diseases there is a naturally occurring disease of domestic rabbits designated venereal spirochetosis caused by a treponeme (*T. cuniculi*) which is morphologically indistinguishable from the human pathogenic

treponemes. The disease is likewise characterized by the development of Wassermann and treponemal immobilizing antibodies ready response to antisyphilitic drugs and some degree of reciprocal immunity to syphilis and yaws. No human infection with this treponeme has been recorded.

## Yaws

**Definition.** Yaws is a specific disease caused by a spirochetal organism *Treponema pertenue*. It is largely limited to tropical countries and is characterized by an initial cutaneous lesion followed by a multiple papular granulomatous skin eruption and in some instances by late destructive lesions of the skin and bones. Lesions of the soles of the feet are especially common. Among synonyms for the disease are *frambesia tropica* *piari* (French) *bouba* (Spanish American) and *parangi* (Ceylon). Many others are listed by Hermans (1931).

**History.** The earliest reliable accounts of yaws now available date to the seventeenth century. Since Negroes were brought from Africa to the West Indies as early as 1510 it cannot be determined whether yaws was introduced into the Americas through this means or whether the disease already existed among the native tribes. Undoubtedly it was prevalent among slaves imported from Africa and by the eighteenth century yaws had become a serious problem on plantations in the West Indies.

**Etiology.** The spirochete of yaws (*T. pertenue*) was first described by Castellani in 1905 soon after the discovery of *T. pallidum* by Schaudinn. The organism measures from 8 to 20  $\mu$  in length and about 0.2  $\mu$  in diameter. It has six to fourteen closely placed spirals and morphologically is indistinguishable from the spirochete of syphilis. It is best seen in the fresh state by darkfield illumination. The organism stains with difficulty.

Among laboratory animals *T. pertenue* is pathogenic for monkeys, rabbits and hamsters, subclinical infection only is produced in mice, rats and guinea pigs. At ordinary temperatures the organism survives for only a few hours when removed from a living host. In special media it will survive for several days but multiplication does not occur. It remains virulent for years when stored at  $-70^{\circ}\text{C}$ . in 15 per cent glycerin.

**Epidemiology.** Distribution and Prevalence. Yaws as an endemic disease is practically limited to the tropics. It is particularly common in equatorial Africa, the West Indies, parts of India, Ceylon, the Philippines, Indonesia and throughout the entire group of Southern Pacific Islands. Endemic foci occur in parts of Brazil and Colombia in South America and in several countries of Central America. Only sporadic cases have been reported from North America and Europe. The disease is not distributed uniformly, however, even within the tropics. The situation as found by the epidemiological studies of the Jamaica Yaws Commission (Turner, Saunders, Kumm and others, 1935, 1937) is interesting and may be representative of that in other countries. In that country the distribution of yaws is uneven. Areas of high prevalence lie within a few miles of communities in which it is rarely encountered and there is a close correlation between its prevalence and certain environmental factors. Where yaws is common there is practically always a heavy rainfall and a fertile moisture holding soil supporting an abundant vegetation.

It is principally a disease of rural peoples, the lowest social and economic groups showing the highest attack rate. There is no clear evidence of racial immunity.

Yaws is usually acquired in childhood but no age is free from the risk of infection. In one community in Jamaica (Bath) prevalence rates rose from 26 per cent among all children under five years of age to 75 per cent among those ten to fourteen years of age. Approximately 90 per cent of all persons found to have infectious lesions were under twenty years of age.

**Transmission.** Yaws can be transmitted by direct person to person contact but it is probable that nonbiting insects also play a role in the spread of the disease. There is no evidence for the existence of an animal or avian reservoir. The initial yaws lesion which develops at the point of implantation of the spirochete is frequently observed at the site of a previous injury and is located on the lower extremity in the majority of cases. Sexual transmission rarely occurs. Transmission from mother to child in utero has not been established.

Since earliest times the possibility of transmission by insects has been recognized. Studies in Jamaica (Kumm and others, 1935, 1936) indicate that in this country a small gnat *Hippelates palipes* is a likely mechanical vector.

**Pathology.** Histologically the cutaneous papule or frambesioma shows marked epi-

FIG 39 Yaws in a child showing generalized frambesiform lesions

thelial hyperplasia elongation of the papillae exudation of leukocytes on or near the surface with many lymphocytes and plasma cells in the dermis Silver stains show spirochetes in large numbers in the epidermis and more superficial dermis The late ulcerative lesions of yaws are histologically similar to syphilitic gummas On the whole the histological criteria for the differentiation of the cutaneous and subcutaneous lesions of yaws and syphilis are unreliable (Ferris and Turner 1937) The occurrence of visceral lesions in yaws is still debated Evidence is accumulating that the aorta is sometimes involved (Choisser 1929 Chambers 1936 Weller 1937) With possibly rare exceptions the central nervous system is not affected

**Clinical Manifestations** *Skin* Within two to eight weeks after infection the initial or primary lesion appears at the point of implantation of yaws spirochetes This lesion is a granuloma and may develop into a large cauliflower like growth from which *T. pertenue* can be recovered There is accompanying enlargement of the regional lymph nodes The initial lesion usually persists for several months and heals with scar formation

During the first weeks of the disease *T. pertenue* gains access to the blood stream

and symptoms attributable to generalization of the organism soon become manifest These consist of widely distributed skin lesions often enlargement of the superficial lymph nodes bone and joint pains and in some cases clinically recognizable lesions of these structures Mild constitutional symptoms such as low grade fever loss of appetite and slight loss of weight may occur but in many cases the general health of the person is not materially affected Within one or two weeks after development of the initial lesion blood serological tests similar to those used in the diagnosis of syphilis (Wassermann Kahn Eagle Hinton) become positive increase rapidly in titer and remain positive for many years unless rendered negative by specific therapy The treponemal immobilization test and other specific treponemal tests also become positive and remain so for many years in untreated patients

The generalized rash may comprise at first only scaly macular lesions More commonly however from the beginning the rash is polymorphous comprising scaly macules folliculopapules papules and most prominent of all large granulomas—the yaw or frambesioma which is characteristic of this disease As the disease progresses the frambesiform lesions become more numerous and larger the patient with a fully developed generalized frambesiform rash presents an arresting picture one which can scarcely be confused with any other disease (Fig 39) The individual lesion stands out from the skin level like a giant wart measuring 0.5 to 4.0 cm in diameter The surface of the lesion which may be covered by a crust is granular like the surface of a raspberry—hence the name frambesia Serum from the lesion yields large numbers of motile *T. pertenue*

After several months retrogression of the generalized lesions may begin The smaller lesions heal and the large frambesiform lesions tend to become smaller and less numerous but it may be many months before they have entirely disappeared Even then relapses are not uncommon so that infectious types of lesions may be present off and on for several years after the onset of the disease Eventually a stage of latency is usually reached but this stage may likewise be interrupted at intervals by the occurrence of more bizarre types of lesions in which *T. pertenue* cannot be readily demonstrated

After several years have elapsed skin lesions similar to the syphilitic gumma may

occur. These so-called "late lesions" are characterized by tissue destruction and ulceration often involving large areas of skin and subcutaneous tissue. *Treponema pertenue* cannot be found but other types of spirochetes notably *Borrelia refringens* may be present. Healing often leads to extensive scarring which if located in the region of a joint may lead to contractures.

Lesions of the soles of the feet are common and account for a good deal of the disability from the disease. Two types which may occur alone or together are recognized. One type consists of one or more crusted papules somewhat analogous to the framboesiform lesion of the skin. Instead of protruding above the plantar surface however the papule lies at the base of a small opening in the sole and is exquisitely tender. Serum from these lesions is usually rich in *T. pertenue*. Like other infectious lesions plantar papules are observed most commonly in the first years of the disease.

The other type of plantar lesions consists of widespread hypertrophy, stripping or fissuring of the superficial layers of the sole and less frequently of the palms giving rise to a curious mottled pattern characteristic of yaws. There is usually no ulceration and *T. pertenue* cannot ordinarily be demonstrated. Plantar hyperkeratosis, the so-called "crab yaws" may occur at almost any period during the course of yaws; it has been observed in patients soon after development of the generalized rash as well as twenty years or more after infection.

**Bones.** In the Jamaica series bone lesions were observed in about 15 per cent of all patients showing active manifestations. On the basis of roentgenographic changes two types are recognized: not infrequently both types are present simultaneously. In the one type periosteal proliferation similar to that seen in syphilis is the most prominent feature. In the other type areas of rarefaction or destruction in the shafts of the long bones are observed. These areas are round or oval and usually multiple with a surrounding zone of increased density. Clinically the patient complains of pain in the affected region and there may be tenderness and swelling of the overlying soft parts (Goldman and Smith 1943; Helfet 1911). The bones of the forearms, legs and hands seem most often to be affected. Involvement of the skull, pelvis and spine is rare. Both periostitis and osteitis may occur either in association with infectious skin lesions or in later years after the generalized skin lesions have healed.

**Other Yaws Lesions.** Among the less common but more spectacular lesions of yaws are gangosa, goundou and juxta articular nodules. In gangosa the cartilaginous and bony structures of the nose are partially or completely destroyed by a late ulcerative process. Cutaneous leishmaniasis may cause somewhat the same picture. Goundou is an egg-shaped paranasal enlargement arising from the superior maxillary bone. The tumors may be sufficiently large to interfere with vision (Strong and Shattuck 1930). Juxta articular nodules are firm freely movable, painless subcutaneous fibroid tumors situated in proximity to a joint.

**Differential Diagnosis.** A case of yaws with typical generalized lesions cannot easily be confused with any other disease. Individual lesions may resemble those of secondary syphilis or cutaneous leishmaniasis but when the case as a whole is considered little difficulty should be experienced. Demonstration of the treponeme in skin lesions serves to differentiate yaws from all conditions except those of the syphilis group. Late ulcerative lesions of yaws are often indistinguishable from the tertiary lesions of syphilis. The late effects of yaws, ulcerative lesions, contractures, partial amputation of digits may resemble the lesions of leprosy. In areas where yaws is common serological tests for syphilis are of limited value in differential diagnosis.

**Prognosis.** The disease is rarely directly fatal except in young infants. Without treatment the disease leads to months of partial incapacity with the possibility of relapses over a period of many years. A not inconsiderable proportion of infected persons apparently go on after many years to spontaneous clinical and serological cure. The indirect mortality from the disease because of secondary infection of cutaneous ulcers or bone lesions is probably higher than is commonly supposed. In areas of high yaws endemicity a substantial proportion of the beds in chronic disease hospitals and poorhouses are occupied by patients whose disability stems primarily from yaws. With early treatment the prognosis is entirely favorable.

**Treatment and Control.** Yaws responds to the same therapeutic agents that are effective in syphilis; it is commonly believed that smaller amounts of drugs are required for yaws but this has not been fully documented. Penicillin is the drug of choice; the tetracyclines have some therapeutic action but are much less effective than pen

Clinically the patient complains of pain in the affected region and there may be tenderness and swelling of the overlying soft parts (Goldman and Smith 1943; Helfet 1944). The bones of the forearms, legs and hands seem most often to be affected. Involvement of the skull, pelvis and spine is rare. Both periostitis and osteitis may occur either in association with infectious skin lesions or in later years after the generalized skin lesions have healed.

**Other Yaws Lesions.** Among the less common but more spectacular lesions of yaws are gangosa, goundou and juxta articular nodules. In gangosa the cartilaginous and bony structures of the nose are partially or completely destroyed by a late ulcerative process. Cutaneous leishmaniasis may cause somewhat the same picture. Goundou is an egg-shaped paranasal enlargement arising from the superior maxillary bone. The tumors may be sufficiently large to interfere with vision (Strong and Shattuck 1930). Juxta articular nodules are firm, freely movable, painless subcutaneous fibroid tumors situated in proximity to a joint.

**Differential Diagnosis.** A case of yaws with typical generalized lesions cannot easily be confused with any other disease. Individual lesions may resemble those of secondary syphilis or cutaneous leishmaniasis but when the case as a whole is considered little difficulty should be experienced. Demonstration of the treponeme in skin lesions serves to differentiate yaws from all conditions except those of the syphilis group. Late ulcerative lesions of yaws are often indistinguishable from the tertiary lesions of syphilis. The late effects of yaws, ulcerative lesions, contractures, partial amputation of digits, may resemble the lesions of leprosy. In areas where yaws is common, serological tests for syphilis are of limited value in differential diagnosis.

**Prognosis.** The disease is rarely directly fatal except in young infants. Without treatment the disease leads to months of partial incapacity with the possibility of relapses over a period of many years. A not inconsiderable proportion of infected persons apparently go on after many years to spontaneous clinical and serological cure. The indirect mortality from the disease because of secondary infection of cutaneous ulcers or bone lesions is probably higher than is commonly supposed. In areas of high yaws endemicity a substantial proportion of the beds in chronic disease hospitals and poorhouses are occupied by patients whose disability stems primarily from yaws. With early treatment the prognosis is entirely favorable.

**Treatment and Control.** Yaws responds to the same therapeutic agents that are effective in syphilis. It is commonly believed that smaller amounts of drugs are required for yaws but this has not been fully documented. Penicillin is the drug of choice; the tetracyclines have some therapeutic action but are much less effective than pen

icillin Use of the arsenical drugs or bismuth is not recommended

Ideally the treatment of yaws should be similar to that of early syphilis in which 2 400 000 units of long lasting penicillin is given intramuscularly at multiple sites One half of this dose is given to children under ten years of age Benzathine penicillin G fortified with procaine penicillin G which is available under a variety of proprietary names is the most satisfactory preparation but procaine penicillin in oil containing 2 per cent aluminum monostearate can also be used in the same dosage In large scale campaigns conducted under the auspices of the World Health Organization a standard dose of 1 200 000 units of one of the foregoing preparations for adults and half that amount for children less than ten years of age have been used with success

The response to penicillin is dramatic Initial and generalized lesions commonly become darkfield negative for *T. pertenue* within forty eight hours and healing is complete within one week Serological titers decline rapidly but a substantial proportion of patients may still show a low titer serological test after six months

Late skin lesions as a rule respond promptly to antiyaws drugs but the more chronic lesions of the skin and bones may require local surgical treatment in addition to chemotherapy

The control program developed by the Jamaica Yaws Commission and subsequently extended and widely applied by the World Health Organization comprised the following (1) survey of the whole population of an area for the purpose of detecting all infectious cases (2) treatment of all cases and the contacts of infectious cases (3) periodic resurveys of the area in order to detect and promptly treat new infections which may arise Since more than 90 per cent of the infectious cases in most areas occur among persons less than twenty years of age it is to this portion of the population that control efforts are particularly directed

**Prophylaxis** No methods of artificial immunization are available In regions where yaws is prevalent the chances of infection can be reduced by avoiding minor injuries to the skin and by protecting all open wounds and abrasions from contamination by flies Children with infectious lesions should be excluded from school until rendered noninfectious by treatment Efforts to control insect vectors are not practicable at the present time

## Bejel

Bejel is a chronic infectious disease of the treponematoses group occurring principally among seminomadic inhabitants of the Arabian Peninsula Asia Minor and the Middle East It is a family disease the infection being acquired usually in childhood with subsequent transmission to adults living in the same tent unless these have been protected by previous infection Drinking utensils often constitute the vehicle of transmission and initial lesions are particularly common about the lips and within the oral cavity Serological surveys indicate that as high as 90 per cent of the inhabitants of some villages are affected

The evolution of the disease follows much the same pattern as that in syphilis and yaws Generalized lesions tend to be confined to the oral cavity and the mucocutaneous borders of the lips genitalia and anal regions The bejel treponeme which is morphologically indistinguishable from *T. pallidum* can be readily demonstrated in early lesions by darkfield examination Bone lesions are common in both the early and late stages roentgenographic examination shows the changes to be similar to those observed in yaws Late lesions of the skin and gummatous involvement of the palate and nasal septum are also common in untreated cases No definitive data are available on the occurrence of visceral lesions

Bejel is an important cause of chronic illness in endemic areas but penicillin is as effective in bejel as in the other treponematoses In the control campaign initiated by the World Health Organization in Iraq good clinical results were obtained with penicillin in aluminum monostearate and oil in one dose of 1 200 000 units given

intramuscularly. A second dose at an interval of three to seven days was given to those with osseous involvement. While the immediate results were good it is not known what proportion of infected persons was cured by this treatment.

## Pinta

(Mal del Pinto Carate)

**Definition** Pinta is a chronic endemic infectious disease characterized by dyschromic papular skin lesions which eventually become depigmented spots.

**Etiology** The disease is caused by a spirochete *Treponema carateum* (also *T. herrejoni*) which is morphologically indistinguishable from *T. pallidum*. This spirochete can be demonstrated in the initial and generalized papular lesions by dark-field examination but not in the depigmented spots. It has not been successfully propagated in laboratory animals or cultivated in vitro.

**Epidemiology** Pinta is endemic in localized areas in Central America and the tropical portions of South America. It has also been reported from the West Indies, tropical Africa and various islands and countries of the South Pacific. Pinta is biologically closely related to syphilis, yaws and other members of the treponematoses group of diseases and in these areas certain diagnostic confusion between pinta and yaws is encountered.

There is no racial immunity. Transmission is usually by direct person to person contact. Intrauterine transmission is believed not to occur. Pinta is acquired mostly by children and young adults but because of its chronic nature many older persons exhibit signs of the disease.

**Pathology** Active lesions appear to be confined to the skin and lymph nodes. The initial and generalized papular lesions are similar histologically being characterized by thickening of the epidermis, dense infiltration of lymphocytes and plasma cells into the dermis with foci of intracellular edema. Perivascular infiltration is usually present. The wide variation in the color of the lesions is a reflection of the degree of vascularity, migration of the chromato-

phores into the more superficial layers of the skin and natural racial variation in skin pigmentation. As lesions grow older there is a progressive decrease in vascular inflammatory cell infiltrate and pigment.

**Symptomatology** In a series of twenty-eight purposeful inoculations of volunteers Leon Blanco found the usual incubation period to be fourteen to twenty days. The initial or primary lesion is papular and enlarges slowly often becoming psoriasiform in appearance with smaller satellite papules. When present alone it may be mistaken for psoriasis or lichenified eczema and its true nature can be established with certainty only by demonstration of *T. carateum*. The regional lymph node is usually enlarged and *T. carateum* can be recovered by aspiration.

The secondary stage which develops in five to twelve months after infection is characterized by a generalized eruption of macules or milium papules called pintids which are often pinkish or violaceous and slightly scaly. Most of these lesions heal but some enlarge and coalesce to form patches resembling psoriasis or lichenoid eczema. They are particularly common on the face and other exposed parts of the body. These lesions are exceedingly chronic and may last for years, often remaining dark-field positive for *T. carateum* all the while. Itching is not a prominent symptom. Hyperkeratosis of the soles and palms also occasionally occurs.

It is this tertiary or dyschromic stage in which the characteristic symptomatology of pinta is observed. When the low grade inflammatory process is still present the lesions usually exhibit some color, sometimes a dull red or violet but more often a leaden or slate blue. As time goes on the active process subsides, the skin becoming atrophic and white because of the loss of pigment. In some patients considerable disfigurement occurs from the extensive areas of vitiligo.

Standard serological tests for syphilis are usually negative during the primary stage of the disease but become positive soon after the appearance of generalized lesions. In the later stages of the disease the serum of nearly all patients gives a positive test, often in high titer. Immobilizing antibody to *T. pallidum* is also present. The only constitutional symptoms are those attributable to a mild chronic infection. Reports of examination of the cerebrospinal fluid have yielded conflicting results, a few observers reporting an increase in cell count in some cases. Likewise the occurrence of

enlargement of the aorta believed to be due to pinta has been reported but the occurrence of such lesions has not been definitely established

**Prognosis** Pinta rarely causes disabling illness or death. Aside from the mild symptoms of a chronic infection the disfigurement due to the dyschromic and achromic lesions with accompanying abnormal psychic reactions is the most serious feature of the disease. The results of penicillin therapy are excellent.

**Treatment** Penicillin is specific. In a series of 700 cases Marquez and his associates observed a dramatic response to one intramuscular injection of 1 200 000 units (4 ml) of penicillin in 2 per cent aluminum monostearate and oil. Other long lasting penicillin preparations (in *Treatment of Early Syphilis*) may be used in the same dosage. Both early papular and late pigmented lesions healed promptly and even the vitiliginous spots if present less than five years often regained pigment. After one year serological tests were negative in about half the patients. When practicable a second injection of the same amount of penicillin should be given one week after the first injection.

## Relapsing Fever

(Recurrent Fever, Famine Fever, Tick Fever, Mianeh Fever, Carapata Disease, Kimputu)

**Definition** Relapsing fever is an acute infectious disease caused by one or another closely related species of spirochetes belonging to the genus *Borrelia*. The disease is characterized by febrile episodes which tend to subside spontaneously and then recur over a period of weeks. Epidemiologically two large groups are recognized, the louse borne which often occurs in large epidemics and the tick borne re-

lapsing fevers which usually follow an endemic pattern. The clinical characteristics of the two tend to be similar.

**History** The first clinical description of the disease was made by Ruttly in 1739. Henderson in 1843 described an epidemic in Edinburgh and differentiated the disease from typhus fever. In 1868 Obermeier discovered the causative spirochete in the blood of relapsing fever patients and was among the first to associate a particular disease with a specific microbial agent. This observation was confirmed by Munch who in 1874 inoculated himself with blood containing motile relapsing fever spirochetes and subsequently acquired the disease and also by Motschutkoffsky (1876) who proved the infectivity of the spirochete by inoculating the blood of patients into healthy persons.

In 1891 Flügge suggested that the human body louse might act as a vector and Mackie (1907) in India reached a similar conclusion. This belief was later confirmed by the inoculation into monkeys of crushed lice taken from relapsing fever patients. In 1904 Ross and Milne in Uganda showed that the tick fever mentioned by Livingston in 1857 was caused by a spirochete which invaded the peripheral blood stream. These observations were confirmed in 1905 in the Congo by Dutton and Todd who reported the mechanism of infection in the tick *Ornithodoros moubata* and the hereditary transmission of the spirochetes through the egg in succeeding generations of ticks.

**Etiology** The spirochete of relapsing fever is classified in the genus *Borrelia*. It is a highly flexible spiral organism varying in length from 8 to 30  $\mu$  in thickness from 0.3 to 0.5  $\mu$  and with five to ten irregular and loosely wound spirals. It is actively motile in the fresh state and stains readily with the ordinary aniline dyes.

Numerous species of relapsing fever spirochetes have been described but these do not differ morphologically from the type species *B. recurrentis* and they all induce essentially the same clinical syndrome in man. Among the species identified have been *B. recurrentis*, *B. obermeieri* and *B. carteri* which are commonly louse borne and *B. duttoni*, *B. hispanica*, *B. lochi*, *B. persica*, *B. turicatae*, *B. pareri*, *B. hermsi*, *B. venezuelense* and *B. neotropicalis* which are commonly tick borne. Differentiation is based largely on the ability of the particular organism to infect a given insect host, consistent antigenic differences have not been found among these varieties of organisms and the validity of identifying many of them as separate species is questionable.

The organisms remain virulent in serum saline at 4° C for about three weeks and survive for long periods when frozen at -70° C. Cultivation on artificial media has been reported but cannot be readily accomplished. *Borrelia* multiply luxuriantly in the

chick embryo Monkeys rats mice and hamsters are readily infected guinea pigs and rabbits are less susceptible It is probable that wild rodents constitute the natural reservoir of infection

Agglutinating immobilizing and bactericidal antibodies are readily demonstrable in the serum of infected persons and may persist for many years On the whole however immunological methods of diagnosis are not very helpful for confusing cross reactions often occur with other organisms Moreover the infecting spirochetes usually show variation in their antigenic structure even during the same attack and the antibody pattern becomes correspondingly complex Some degree of immunity appears to follow a clinical attack but data on this point are inadequate Attempts to immunize animals with killed relapsing fever spirochetes have been unsuccessful

**Epidemiology** Relapsing fever has been reported from nearly all parts of the world at one time or another Its occurrence is largely dependent upon the presence of effective insect vectors especially the body louse and certain species of ticks and upon the existence of environmental factors that favor contact between vector and man Great epidemics of louse borne relapsing fever have swept through central and southeast Europe North Africa and parts of China during the past few decades often occurring concurrently with typhus fever Tick borne relapsing fever is endemic in many parts of the world in the United States sporadic cases have been observed in several of the western and west-central states

**Transmission** Relapsing fever can be transferred by the inoculation of blood from an infected person but under natural conditions the disease is transmitted by blood sucking arthropods especially lice and ticks although fleas and bedbugs have also been incriminated as vectors

In lice ingested spirochetes quickly enter the hemocoel and become abundant from the fourth day infective spirochetes persist for weeks and probably for the rest of the louse's life There is no transovarian transmission The disease is probably transmitted to man not by the bite of the louse but by crushing it infection occurring through the skin or by way of the hands to the conjunctiva

Tick borne relapsing fevers are transmitted principally by the genus *Ornithodoros* and a score of species have been incriminated as vectors Ingested spiro-

chetes quickly disappear from the digestive tract of the tick but reappear within several days in the malpighian tubules coxal glands salivary glands and legs Human infection probably occurs both through the bite of the tick and by contamination of the human skin with fecal fluid of the tick Spirochetes are transmitted from adult female ticks through the eggs to their offspring for at least several generations

**Pathology** Relapsing fever spirochetes are found in the peripheral blood during the acute attacks but suddenly disappear just prior to the crisis On the basis of animal experiments it seems likely that spirochetes are present in the internal organs particularly the spleen and brain during periods of remission and it is at these sites in which *Borrelia* can usually be demonstrated at autopsy in man The histopathological changes are not diagnostic The crisis remission and subsequent relapse are reflections of a host parasite interplay in which the development of antibody to the spirochete persistence and later multiplication of antigenic variants of the original strain and the development of new specific antibodies proceed in a cyclic manner It appears likely that death is caused more frequently by complicating conditions and infections than by relapsing fever *per se* but specific deaths may be due to hemorrhagic cerebral lesions meningitis hepatitis or rupture of the spleen

**Clinical Manifestations** There is considerable variation in symptoms from one outbreak to another and in different patients in the same outbreak No symptom-complex is uniquely associated with a particular species of relapsing fever spirochete or with the mode of transmission

The incubation period usually varies from two to fifteen days the average being about seven days

The initial attack which may last two to eight days commonly starts abruptly with chilliness or a chill followed by high fever intense headache pains in the muscles and joints often nausea and vomiting photophobia bronchitis with a troublesome cough and sometimes epistaxis The temperature rises quickly to 104° or 105° F (40° to 40.5° C) and except for slight morning remissions it remains elevated throughout the initial febrile period at the end of which it falls by crisis The pulse is usually rapid 120 to 140 beats per minute during the febrile period Sweating may be profuse during the first day but thereafter the skin is usually

hot and dry and the face flushed. Jaundice may occur but is more likely to appear later. An erythematous rash is common during this period and later rose colored spots may appear on the trunk and limbs. Petechiae may occur which resemble those of typhus fever or early hemorrhagic smallpox. Labial herpes is not uncommon.

In severe cases neurological and psychic disturbances similar to those occurring in typhus fever are observed. Intense headache, delirium—especially accompanying high fever—and hyperesthesias of the taste and tactile senses may occur. Rarely hemiplegia, aphasia or symptoms resembling encephalitis or meningitis are observed. In such cases there is commonly an increase in lymphocytes in the cerebrospinal fluid in which spirochetes may be demonstrated.

In addition to severe myalgia and arthralgia, abdominal pain with or without nausea and vomiting may be a prominent feature and gastric hemorrhages have been reported. The liver and spleen are usually enlarged and tender.

During the acute febrile periods there is a polymorphonuclear leukocytosis of 15 000 to 20 000 per cu mm and the Arneth count is shifted to the left. In about 20 per cent of cases serological tests for syphilis are positive and the Weil-Felix test may be positive in titers of 1:80 or higher. The spirochetes of relapsing fever are commonly demonstrable in the blood during the febrile periods and have also been demonstrated in the urine and prostatic fluid. Albuminuria is common during the acute attacks. Casts and erythrocytes are less frequently observed.

The initial attack usually ends by crisis accompanied by profuse sweating and a rapid fall in temperature to normal or below. In elderly or weak patients a dangerous state of collapse may occur. Diarrhea at this time is not uncommon.

The period of remission which follows the initial attack lasts three to ten days. The temperature remains normal. Although prostration is great at first the appetite and strength soon return and the patient may consider himself completely recovered. Spirochetes can no longer be found in the peripheral blood.

A relapse follows this symptomless interval in most untreated cases. It is characterized by a repetition of the more important symptoms of the initial attack except that as a rule they are milder. Focal lesions such as jaundice, conjunctivitis, iritis, transient cranial nerve abnor-

malities and uterine hemorrhages are more common. The relapse seldom lasts as long as the first attack and it also ends by crisis.

Additional relapses may occur but are less common. When they occur they are usually shorter and milder than the previous febrile periods. As many as eleven relapses over a period of four months have been recorded. In many cases convalescence is protracted and there may be various sequelae including iritis, otitis, parotitis, adenitis, neuritis, arthritis, nephritis and pneumonitis.

**Diagnosis.** The final diagnosis of relapsing fever except in epidemic periods rests upon the demonstration of *Borrelia* in the peripheral blood. Serological tests are unreliable because of confusing cross reactions with *Spirochetes* which are more numerous early than late in the febrile attack can be demonstrated in the blood in wet films preferably by darkfield illumination but may be seen under the light microscope. They may also be demonstrated in films stained with Wright or Giemsa stains and when these methods fail by inoculation of rats or mice. Inoculation is made intraperitoneally with 0.2 to 0.5 ml of whole or citrated blood and the animal's blood is examined from the second to seventh day for the presence of *Borrelia*.

The relapsing fevers may be confused with various other acute infections including malaria, dengue, typhus, influenza, leptospirosis and early smallpox. Clinical differences frequently emerge as the acute attack progresses but definitive diagnosis depends upon the demonstration of spirochetes in the blood.

**Prognosis.** Relapsing fever in untreated patients may last for three to twelve weeks. Case fatality rates vary from 2 to 8 per cent, being highest among the malnourished and aged. With specific and good supportive treatment the acute attack is cut short, relapses are largely eliminated and recovery is rapid.

**Treatment.** Supportive treatment in the form of bed rest, ample fluids and a soft or liquid diet should be given. The arsenicals, particularly the neoarsphenamines which previously were the specific treatment of choice, have been superseded by various other antimicrobial drugs, principally penicillin and the tetracyclines.

Crystalline penicillin should be given in aqueous solution every three hours for at least five days in a total dose of 1 000 000 units per day. Failures have been attributed to inadequate dosage.

The treatment of choice is chlortetra-

cycline in doses of 0.5 gm every six hours for five days then 1.0 gm twice daily for another five days. Children under ten years of age should be given half of these doses. Oxytetracycline in approximately the same dosage as chlortetracycline seems to be equally effective on the basis of more limited trials. chloramphenicol in doses of 250 to 500 mg at three hour intervals for a total of four doses has also been found to be effective. With all of these drugs an initial Herxheimer like reaction may occur with marked exacerbation of symptoms.

**Prevention** Since transmission of the disease in nature occurs only through arthropod vectors preventive measures should be directed toward protection against these insects. No effective vaccine is available and chemoprophylactic measures are not practicable. The louse borne disease can be prevented by taking all of the precautions necessary to avoid exposure to body lice or head lice. These measures include the maintenance of good personal hygiene and cleanliness and the disinfection of louse infested persons and clothing. During World War II 10 per cent DDT powder was highly effective in controlling louse infestation but DDT resistant strains of lice have subsequently developed in many areas so that this form of control is now less dependable.

The tick borne infections are more difficult to control since these arthropods do not live on the victim. As a rule they live in the floors or walls of native houses in the earth of old camp sites in cracks in the floors and walls of caves and in the burrows of various small animals. Infested places should not be selected as camp sites and care should be taken to avoid exposure to ticks which usually come out of their hiding places at night and feed on their hosts.

Some success in tick control within houses has been reported through the use of an aqueous suspension of benzene hexachloride in a dose of 15 mg of active substance per square foot of floor treated. Two applications are made at four to six week intervals.

## Tropical Ulcer

Acute and chronic ulcerative processes usually involving the foot or the lower third of the leg are common in rural tropical areas and in many localities constitute the most common single condition encountered in both outpatient clinic and hospital practice. A number of different clinical types can be recognized some constituting clear etiological entities as for example yaws, leprosy, diphtheria and varicose ulcers to mention only a few.

There is however a common type of acute phagedenic ulcer the clinical appearance and evolution of which are sufficiently characteristic to warrant its classification as a distinct clinical entity under the name of Tropical Ulcer. It occurs much more frequently in children and adults under thirty years of age than in older persons and is more common in males than in females. It affects enormous numbers of people causing massive suffering and economic loss.

The etiology of tropical ulcer remains in dispute. Trauma often minor appears to play an important role in its inception. Spiral organisms belonging to the genus *Borrelia* and perhaps closely related to *B. vincenti* together with *Bacillus fusiformis* are found in a majority of recently developed ulcers but whether these organisms are the primary inciting cause or secondary invaders has not been determined. There is impressive clinical and epidemiological evidence suggesting that a dietary protein deficiency particularly in the vitamin A complex is an essential predisposing factor. From tropical ulcers of a weeks duration or longer many varieties of microorganisms can be cultivated commonest among which are proteus bacilli, staphylococci and beta hemolytic streptococci.

Clinically tropical ulcer is characterized by rapid destruction of tissue as though

some autolytic agent were present. Beginning as a small abraded or ulcerated area 0.5 to 1.0 cm in diameter within twenty-four hours there may be a deep circular ulcer with undermined edges measuring 2.0 to 5.0 cm in diameter. The margins are not indurated or greatly swollen and the base tends to bleed easily when probed. Pain is usually less than the destruction of tissue would portend. There is often a foul odor. The stage of rapid progression usually terminates within two to five days but the ulcer may persist for months and at times may extend more slowly to involve underlying bone or adjacent areas of skin and subcutaneous tissue.

Whatever the initial infecting agent may be, continued progression or persistence of the lesion seems clearly to be due in most instances to bacteria which are susceptible to the broad spectrum antimicrobial drugs. Treatment with penicillin, tetracycline and oxytetracycline has been reported to be effective especially in the early stages before the wide destruction of dermal tissues. Penicillin should be administered in a long-lasting preparation 1,200,000 units intramuscularly for adults and 600,000 units for children under ten years of age. One injection is usually sufficient. Tetracycline and oxytetracycline have been used successfully in doses of 1.0 to 1.5 gm daily for four to seven days. Antimicrobial therapy should be accompanied by local cleansing of the lesion and by increase in dietary proteins. Skin grafting is often necessary in large ulcers and in certain areas itinerant skin grafting teams have been organized for this service. Preventive measures include health education directed to the correction of protein deficiency and to the hygienic care of minor injuries of the lower extremities, protective clothing to prevent minor injuries and insect bites especially in troops, and prompt antimicrobial treatment of developing ulcers.

## Rat Bite Fever

Two etiological and clinical entities are included in the medical literature under the term rat bite fever: the only important factor common to both being the usual mode of transmission to man indicated by the name. The two diseases will be designated respectively *spirillary rat bite fever* and *streptobacillary fever* in accordance with the nature of the etiological agent of each (Watkins).

**History.** Transmission of a febrile disease to man by the bite of a rat has been known for centuries. The first clinical description of the disease was by Wilcox in 1840 and a monograph by Miyake in 1900 awakened interest in the disease. In 1914 Schottmüller isolated a streptobacillus from a case of rat bite fever and in 1916 Futaki and his associates demonstrated a spirillum. Cases have been reported from many parts of the world. Watkins collected 184 cases reported in the United States up to 1946 of these a streptobacillus was demonstrated in 39 and a spirillum in 41. Since 1946 most of the cases reported have been of the streptobacillary type. No case has been reported in which both etiological agents were demonstrated to be present simultaneously although such cases may plausibly occur.

## SPIRILLARY RAT BITE FEVER (Sodoku)

**Definition.** The disease caused by *Spirillum minus* is characterized by an indurated ulcer at the site of inoculation, regional lymphadenitis, relapsing type of fever, skin rash and often false positive serological tests for syphilis.

**Etiology.** Of thirty-nine proved cases recorded by Watkins, thirty-seven followed the bite of a rat, one the bite of a weasel and one simple trauma with no known animal contact. This is in contrast to Weil's disease which is rarely transmitted by actual rat bite. The source of the spirilla at the time of rat bite is believed to be the eye discharge produced by keratoconjunctivitis of the infected rat; this discharge in which spirilla have been demonstrated drains into the oral cavity of the rat.

*Spirillum minus* is a short, thick spiral organism 2 to 5  $\mu$  in length with one to three angular curves and polar flagellae. It moves with a rapid darting motion which can best be seen by darkfield microscopic examination. It cannot be cultivated in artificial media but upon intraperitoneal inoculation of laboratory animals (guinea pigs, rats, mice) blood stream invasion and peritoneal involvement occurs. In guinea pigs intradermal inoculation often gives rise to a local lesion in which the spirillum can be demonstrated.

**Clinical Manifestations** Unless complicated by secondary infection the rat bite wound heals promptly. After an incubation period of five to twenty-eight days there is sudden onset with flare up of the rat bite wound, regional lymphangitis and lymphadenitis, chills, fever, malaise and headache.

The site of inoculation becomes swollen, indurated, painful, with an angry purplish hue and may subsequently ulcerate. After several days both local and generalized symptoms subside only to reappear again in a few days. Periods of fever may then alternate with afebrile periods, the temperature rising abruptly and remaining elevated for twenty-four to forty-eight hours then falling rapidly to normal.

This relapsing type of fever is typical and may continue for weeks in untreated cases. The first few relapses are usually accompanied by an exacerbation of the inflammation in the wound and the appearance of a rash. The eruption is of a dusky red macular or maculopapular character and is sparsely distributed over the trunk and extremities. The spleen is often palpable. Arthritis is not a common or prominent symptom in contrast to streptobacillary fever, although arthralgia and muscle pains may occur. A leukocytosis is often but not invariably present and may reach 20,000 or more per cu mm. False positive serological tests for syphilis occur in a high proportion of cases. The fatality rate as recorded has been about 10 per cent but this should be reduced by modern therapy.

**Diagnosis** Confirmation of the diagnosis is made by demonstration of *Spirillum minus*. Exudates from the local lesion and material aspirated from the enlarged regional lymph node should be examined by darkfield microscopy and inoculated into the scrotal skin of guinea pigs or intraperitoneally in mice. Darkfield examination of blood is unrewarding, but freshly drawn blood plasma should be inoculated intraperitoneally in guinea pigs and mice. Spirilla may be demonstrated by darkfield examination of the animal's blood and peritoneal exudates five to fourteen days after inoculation. As both mice and guinea pigs occasionally carry spirilla as a natural infection, an effort should be made to demonstrate the organism in more than one inoculated animal.

**Treatment** In the pre-antibiotic era the response to the arsenical drugs, such as neosphenamine, was usually prompt. Antibiotics are now the drugs of choice: penicillin, streptomycin and the tetracy-

clines all apparently having therapeutic activity. Crystalline penicillin in doses of 30,000 to 40,000 units every six hours for seven days has proved to be satisfactory. Penicillin in aluminum monostearate or other long-lasting penicillin preparations administered intramuscularly in a single dose of 1,200,000 units should also be effective. Streptomycin in doses of 0.5 gm for adults and 0.25 gm to 0.1 gm for children given twice daily for three to four days has also been shown to be effective.

Chlortetracycline and oxytetracycline in an initial dose of 10 mg per kg of body weight with daily maintenance doses of 30 mg per kg given orally has been recommended.

### STREPTOBACILLARY FEVER

(Haverhill Fever, Erythema Arthriticum, Epidemicum)

**Definition** Streptobacillary fever is an acute infection acquired often but not exclusively by rat bite and characterized by acute onset, intermittent fever, erythematous rash and polyarthritides.

**Etiology** *Streptobacillus moniliformis* is a gram-negative pleomorphic organism 2 to 15  $\mu$  in length which grows in chains interspersed with swollen bodies among the bacillary forms. It is a common inhabitant of the nasopharynx of wild and laboratory rats and most cases of this disease have followed the bite of a rat. However, one epidemic originally described as Haverhill fever (Place and Sutton) was milk-borne and there have been a number of sporadic cases reported in which no direct contact with rats could be established.

**Clinical Manifestations** The incubation period is usually one to five days, tending to be shorter than in spirillary rat bite fever. If the disease follows rat bite, the local wound ordinarily heals without incident but occasionally an abscess develops in the wound. Regional lymphadenitis is not a prominent feature. The onset of the disease is abrupt with chills, fever, vomiting, headache and rather severe pains in the back and joints. A maculopapular rash develops early, usually within the first forty-eight hours and at this stage the disease is dengue-like in its manifestation. Often there is a remission of the fever after forty-eight to seventy-two hours. Within the first five days, however, one or more joints usually become swollen, red and painful with recurrence of the septic type of fever. The acute arthritis is one of the most prominent and persistent symptoms in streptobacillary fever. Subcutaneous

abscesses from which the infecting organism has been recovered have been observed. Bronchopneumonia also occurs in a small proportion of cases. There is a leukocytosis of 10 000 to 20 000 cells per cu mm with a relative increase in neutrophils. False positive serological tests for syphilis occur only rarely in contrast to spirillary rat bite fever.

Relapse is rare but in the absence of specific therapy convalescence may be prolonged because of the affected joints. About 7 per cent of reported cases have been fatal but this proportion can probably be substantially reduced by modern therapy. Ulcerative endocarditis and myocardial abscesses have been found post mortem.

**Diagnosis.** Even without a history of rat bite an acute febrile illness accompanied by nonmigratory polyarthritides and skin rash is highly suggestive of streptobacillary fever. Serum agglutinins for *Streptobacillus moniliformis* develop within ten days and reach a maximum in three to four weeks. An agglutination titer of 1:80 or higher is regarded as diagnostic demonstration of a four fold or greater rise in titer is especially significant. *Streptobacillus moniliformis* may be recovered from the patient's blood or more readily from fluid aspirated from an affected joint or abscess. Isolation is accomplished by implantation in special media containing serum or ascitic fluid or by intraperitoneal inoculation of mice. Infection is usually fatal to mice in six to twelve days and the organism can in turn be demonstrated in their blood. In liquid or semisolid media colonies develop well below the surface of the medium and have a characteristic fluffy cotton ball appearance. Mice which survive the infection frequently develop joint lesions from which the organism can be isolated.

**Treatment.** Penicillin appears to be specific for this disease although relatively few cases have been reported since this drug has been available. In the absence of more definitive information large doses of penicillin 1 200 000 units per day of the aqueous form for adults and older children and one half this amount for young children should be given daily for at least seven days. Further experience may show smaller doses to be effective.

Streptomycin in a dose of 10 to 20 gm daily until the patient has been asymptomatic for two to three days has also been found to be effective. No data are available on the efficacy of the other antimicrobial drugs. In contrast to spirillary rat bite fever

the arsenical drugs are not effective in the streptobacillary disease.

## The Leptospiroses

**Definition.** The leptospiral infections of man comprise a group of syndromes including Weil's disease, pretibial fever, meningitis, nephritis, arthritis, endocyclitis and a mild grippelike illness.

More than twenty different strains of leptospires have been recognized by serological methods. The strains known to be associated with human infection in the United States include *L. icterohemorrhagiae*, *L. canicola*, *L. pomona*, *L. autumnalis* and *L. grippityphosa*.

**Epidemiology.** A variety of wild and domestic animals including rats, mice, dogs, cattle and swine may become infected by leptospires and the infection is usually chronic, characterized by excretion of living organisms in the urine for long periods of time. Humans may become infected by contact with materials contaminated by such urine for this reason certain occupations carry a special hazard of leptospiral infection. These include sewer work, ditch digging, fish cutting, farming and slaughterhouse work. Infection has also been acquired from swimming in pools of contaminated water.

**Pathogenesis and Pathology.** The portal of entry is believed to be either the respiratory or the gastrointestinal tract although conceivably leptospires can gain access through cuts or abrasions of the skin. Once the organisms have penetrated the mucosal or skin barrier the type of clinical disease produced will depend upon the strain of in

fecting organism as well as upon the host's response. In young persons the *mild grippelike* and *meningeal* forms of disease are more likely to develop whereas in persons past the age of thirty the more severe *Weils disease* is commonest. This form is most frequently associated with infection by *L. icterohemorrhagiae* although it is occasionally produced by *L. canicola*.

Presumably in all forms of infection there is an initial leptospiremia. This can be demonstrated in the great majority of cases of *Weils disease* any time during the first three to five days of illness. Circulating antibodies usually make their appearance during the second week of illness and organisms can seldom be demonstrated in the blood after that time. *Leptospirae* may appear transiently in the urine during the latter part of the second or the third week. A chronic urinary carrier state does not become established in the human as it so frequently does in animals.

The cellular response to acute inflammation produced by leptospirae varies. The muscle lesions of *Weils disease* are principally those of acute localized degenerative changes in muscle fibers with little inflammatory reaction about them. In the liver the microscopic evidence of disease is often surprisingly meager even in deeply jaundiced patients. There may be minimal evidences of cytoplasmic degeneration, some active hepatocellular regeneration and bile stasis. In the most severe cases areas of focal necrosis may be observed. In the kidney the pathological changes may be more obvious; here one finds degeneration and necrosis of convoluted tubules, diffuse interstitial inflammation and numerous granular casts and cellular debris in the collecting tubules. The cellular response in meningitis is principally lymphocytic. The circulating leukocytes of the blood vary in number according to the disease picture. In the grippelike meningeal and pretibial fever syndromes, the leukocyte count is usually in the normal range whereas in *Weils disease* a well marked leukocytosis is the usual finding.

#### WEIL'S DISEASE

**Clinical Manifestations.** The incubation period is usually eight to twelve days. The onset is abrupt, often with one or more chills followed by fever varying from 102° to 104° F. Headache and photophobia are prominent symptoms and the patient complains of severe muscular pains in the lumbar region and calves. There may be nausea, vomiting or diarrhea. Sore throat

and cough are less common. The conjunctivas are conspicuously injected. Herpes simplex may develop about the mouth. The spleen seldom becomes palpably enlarged.

Fever usually lasts four to seven days then terminates by rapid lysis. There may however be no real improvement in the clinical state since it is at about the fifth or sixth day that hepatitis and nephritis are likely to become obvious. About 60 to 70 per cent of cases recognized as having *Weils disease* show hepatitis with icterus and enlarged tender liver. Jaundice deepens during the next few days then usually begins to subside by the twelfth or fourteenth day. In cases terminating fatally there may be increasing cholemia until death. Nephritis is somewhat less frequent, being evident in less than half of the recognized cases. It is manifested by albuminuria and hematuria and in severest cases by oliguria and azotemia. Renal involvement is rare without evidence of liver disease. In about 10 per cent of cases there is clinical evidence of meningeal inflammation, i.e., pain and stiffness of the neck, with Kernig's and Brudzinkski's signs. Other unusual manifestations include petechial and purpuric lesions of the skin and iridocyclitis or optic neuritis.

Relapse with fever and muscle pain occurs in about 20 per cent of all cases during the third or fourth week. The symptoms are usually milder than in the original attack.

**Diagnosis.** *Leptospirae* have been identified in the blood by darkfield microscopy during the first five to seven days of illness. This procedure is reliable only in the hands of an experienced observer since it is easy to mistake strands of fibrin moved about by brownian motion for leptospirae. A preferable procedure is to inoculate young guinea pigs intraperitoneally with the patient's blood. These animals show signs of infection (fever and jaundice) three to fifteen days later and the organisms can be recovered from their tissues. After the first week of illness it is rarely possible to demonstrate leptospirae in the blood but during the second or third week they may be recovered from the urine by animal inoculation in perhaps 20 per cent of cases. Occasionally leptospirae can be recovered from the blood or urine of human beings by cultural methods.

**Antibodies** usually appear in the blood during the second week of illness and reach peak levels by the third or fourth week. Agglutinin titers of 10,000 to 100,000 are not uncommon. For best results the antigen

abscesses from which the infecting organism has been recovered have been observed. Bronchopneumonia also occurs in a small proportion of cases. There is a leukocytosis of 10 000 to 20 000 cells per cu mm with a relative increase in neutrophils. False positive serological tests for syphilis occur only rarely in contrast to spirillary rat bite fever.

Relapse is rare but in the absence of specific therapy convalescence may be prolonged because of the affected joints. About 7 per cent of reported cases have been fatal but this proportion can probably be substantially reduced by modern therapy. Ulcerative endocarditis and myocardial abscesses have been found post mortem.

**Diagnosis.** Even without a history of rat bite an acute febrile illness accompanied by nonmigratory polyarthritides and skin rash is highly suggestive of streptobacillary fever. Serum agglutinins for *Streptobacillus moniliformis* develop within ten days and reach a maximum in three to four weeks. An agglutination titer of 1:80 or higher is regarded as diagnostic demonstration of a four fold or greater rise in titer is especially significant. *Streptobacillus moniliformis* may be recovered from the patient's blood or more readily from fluid aspirated from an affected joint or abscess. Isolation is accomplished by implantation in special media containing serum or ascitic fluid or by intraperitoneal inoculation of mice. Infection is usually fatal to mice in six to twelve days and the organism can in turn be demonstrated in their blood. In liquid or semisolid media colonies develop well below the surface of the medium and have a characteristic fluffy cotton ball appearance. Mice which survive the infection frequently develop joint lesions from which the organism can be isolated.

**Treatment.** Penicillin appears to be specific for this disease although relatively few cases have been reported since this drug has been available. In the absence of more definitive information large doses of penicillin 1 200 000 units per day of the aqueous form for adults and older children and one half this amount for young children should be given daily for at least seven days. Further experience may show smaller doses to be effective.

Streptomycin in a dose of 1.0 to 2.0 gm daily until the patient has been asymptomatic for two to three days has also been found to be effective. No data are available on the efficacy of the other antimicrobial drugs. In contrast to spirillary rat bite fever

the arsenical drugs are not effective in the streptobacillary disease.

## The Leptospiroses

**Definition.** The leptospiral infections of man comprise a group of syndromes including Weil's disease, pretibial fever, meningitis, nephritis, arthritis, iridocyclitis and a mild grippelike illness.

More than twenty different strains of leptospires have been recognized by serological methods. The strains known to be associated with human infection in the United States include *L. icterohemorrhagiae*, *L. canicola*, *L. pomona*, *L. autumnalis* and *L. grippotyphosa*.

**Epidemiology.** A variety of wild and domestic animals including rats, mice, dogs, cattle and swine may become infected by leptospires and the infection is usually chronic, characterized by excretion of living organisms in the urine for long periods of time. Humans may become infected by contact with materials contaminated by such urine. For this reason certain occupations carry a special hazard of leptospiral infection. These include sewer work, ditch digging, fish cutting, farming and slaughterhouse work. Infection has also been acquired from swimming in pools of contaminated water.

**Pathogenesis and Pathology.** The portal of entry is believed to be either the respiratory or the gastrointestinal tract, although conceivably leptospires can gain access through cuts or abrasions of the skin. Once the organisms have penetrated the mucosal or skin barrier, the type of clinical disease produced will depend upon the strain of in

only on the anterior aspects of the legs (hence the name "pretibial") but is occasionally generalized even to the face. The lesions consist of irregular slightly raised areas of erythema varying in size and shape occasionally being 5 cm in diameter.

The course of illness is brief fever subsiding in four to eight days and there are no residual defects.

The distinctive laboratory finding is leukopenia in the early stages with return to normal levels in convalescence.

Definitive diagnosis can be made by isolating *L. autumnalis* from the blood during the early stage of illness or by demonstrating the appearance of specific antibodies for that organism during convalescence.

#### LEPTOSPIRAL MENINGITIS (Swineherd's Disease)

This form of leptospirosis is most commonly observed in young persons and there is a peak incidence in the latter part of the summer. It was first described in Europe where it was called swineherd's disease. For a time it was thought to be due to a virus similar to that of lymphocytic choriomeningitis but the leptospiral etiology has since been established beyond doubt. Cases have been shown to be caused by *L. icterohemorrhagiae*, *L. canicola* and *L. pomona*. The clinical picture is indistinguishable from that of other nonpurulent meningitides caused by viruses such as lymphocytic choriomeningitis, mumps and nonparalytic poliomyelitis. There is usually an abrupt onset of illness with headache, fever, pains in the muscles, some stiffness of the back and neck. The temperature may go as high as 103 or 104° F. The cerebrospinal fluid may be normal during the first two or three days; later a mononuclear pleocytosis develops, the cell count usually being between 50 and 300 with occasionally as many as 50 per cent being polymorphonuclears. Dextrose content of the cerebrospinal fluid is normal and the protein is moderately elevated, usually being 50 to 100 mg per 100 ml. The peripheral leukocyte count is normal. Symptoms of headache and malaise persist for two to ten days then subside and complete recovery ensues. Diagnosis can be made only by isolation of leptospirae from the blood or cerebrospinal fluid or by serological tests.

#### GRIPPE LIKE ILLNESS AND OTHER FORMS OF LEPTOSPIRAL INFECTION

**Grippe like illness.** In many parts of the world leptospiral infection is commonly observed in the form of a brief febrile disease without localizing manifestations pointing either to hepatic or to meningeal involvement. These infections are usually caused by strains of leptospirae other than *L. icterohemorrhagiae* such as *L. canicola*, *L. pomona* and *L. grippotyphosa*. According to the occupational factors these diseases are designated variously as rice field fever, mud fever, cane fever and so forth. There are no distinctive manifestations and diagnosis can be made only by demonstration of the agent in the blood or urine or by serological methods. In a case recently reported from Tennessee in addition to the above symptoms of fever and malaise there was an acute polyarthritis with a clinical picture somewhat suggestive of acute rheumatic fever.

**Iridocyclitis.** Acute inflammation of the iris and uveal tract may occur as a late complication of Weil's disease usually coming on in the third or fourth week but sometimes as an isolated entity several months after recovery from generalized leptospiral infection. Such cases may come under the care of ophthalmologists and the relationship to the preceding leptospiral infection may not be recognized because of the long latent period which has occurred. The outcome is usually satisfactory with subsidence after two or three weeks leaving no permanent damage to the eye.

**Nephritis.** In rare instances leptospiral infection is principally manifested by involvement of the kidney with hematuria, proteinuria, cylindruria and oliguria. Such a picture can easily be confused with that of acute glomerulonephritis. The eventual outcome is complete recovery.

should be freshly prepared from cultures

In the blood a polymorphonuclear leukocytosis from 10 000 to 30 000 per cu mm is the rule. This is of considerable value in differential diagnosis. There may be a moderate reduction in blood platelets although not usually sufficient to account for the hemorrhagic tendency sometimes manifested. Examination of the cerebrospinal fluid is a useful guide to diagnosis of Weil's disease. In 80 to 90 per cent of all cases regardless of the presence of clinical signs of meningitis there is a pleocytosis varying from 10 to several hundred cells per cu mm the majority being lymphocytes. In patients with jaundice the cerebrospinal fluid also becomes xanthochromic. The urine may show no abnormality during the first few days but with the development of hepatitis bilirubin may appear. Nephritis is evidenced by hematuria cylindruria and proteinuria.

Muscle biopsy can also provide an early presumptive diagnosis of Weil's disease for the tissue obtained may reveal a characteristic picture consisting of areas of focal necrosis in a segment of muscle fiber with little vascular change or infiltration by inflammatory cells.

**Differential Diagnosis.** During the first few days of illness the picture is that of an acute systemic infectious disease which can hardly be differentiated from a variety of other processes including acute pyogenic infections, influenza and typhus fever. Severe muscle pain, suffusion of the conjunctivas, leukocytosis and pleocytosis in the cerebrospinal fluid are features which should suggest leptospiral infection. After the first week there may be little or no fever but jaundice is likely to appear. At this stage the principal problem is differentiation from viral hepatitis. Again the presence of conjunctival suffusion, leukocytosis and cerebrospinal fluid abnormalities are helpful. In acute hemolytic jaundice reticulocytosis is likely to be present and bile may not be found in the urine.

**Prognosis.** The fatality rate is approximately 5 per cent in recognized cases of Weil's disease. As many mild forms of the disease probably go unrecognized the actual death rate is doubtless considerably lower. The prognosis is grave if there is severe hepatic and renal involvement with deep jaundice, azotemia, oliguria or circulatory impairment.

**Treatment.** General supportive measures to be used in acutely ill patients are the same as for any acute infectious disease.

It has been difficult to evaluate different kinds of specific therapy in Weil's disease because of its variable severity and natural early subsidence of fever. In view of good results in the treatment of experimental infection with antiserum, a few attempts have been made in humans to give serum therapy or transfusions of blood from patients who have recovered from the infection. The results have not been clear-cut and neither procedure has been widely accepted.

Penicillin is effective in therapy of experimental infections if given early in the course of the disease but not after the infection has become well established. The drug has been administered more or less routinely to patients with Weil's disease since 1944 but its value still remains questionable. Deaths have occurred despite administration of moderately large doses of the drug. The tetracyclines and chloramphenicol are also effective in experimental infections but their usefulness in treatment of human disease has not been clearly demonstrated. In a study of various antimicrobial drugs alone and in combination carried out in Puerto Rico there was no definite benefit demonstrable with any.

#### PRETIBIAL FEVER (Fort Bragg Fever)

An acute infectious disease which was observed among soldiers stationed at Ft. Bragg, North Carolina during the period 1942-1944 was given the names pretibial fever and Fort Bragg fever. An agent probably responsible for the disease was isolated from the blood of a patient in 1944 and maintained by animal passage in laboratories for some years thereafter. Originally assumed to be a filterable virus, this agent was shown in 1952 by Gochenour and associates to be *L. autumnalis*. The serum saved from patients convalescent from pretibial fever was found to contain specific agglutinins for this agent. Sporadic cases of the syndrome are still observed occasionally in North Carolina and in Georgia and it is to be presumed that the disease still occurs in those regions.

The clinical manifestations are those of an acute self-limited exanthematous infectious disease. There is an abrupt onset with chilliness or chills, malaise, headache and photophobia. Some patients have cough and coryza, some have nausea and vomiting. On examination the distinctive physical findings are splenomegaly and a cutaneous eruption. The rash appears about the fourth day of illness. It is most often located

only on the anterior aspects of the legs (hence the name pretibial) but is occasionally generalized even to the face. The lesions consist of irregular slightly raised areas of erythema varying in size and shape occasionally being 5 cm in diameter.

The course of illness is brief fever subsiding in four to eight days and there are no residual defects.

The distinctive laboratory finding is leukopenia in the early stages with return to normal levels in convalescence.

Definitive diagnosis can be made by isolating *L. autumnalis* from the blood during the early stage of illness or by demonstrating the appearance of specific antibodies for that organism during convalescence.

#### LEPTOSPIRAL MENINGITIS (Swineherd's Disease)

This form of leptospirosis is most commonly observed in young persons and there is a peak incidence in the latter part of the summer. It was first described in Europe where it was called swineherd's disease. ## PROTOZOAN INFECTIONS

### Amebiasis

**Definition** Amebiasis is the disease caused by infection with the protozoan *Endamoeba histolytica*. It affects the colon primarily and other organs secondarily especially the liver. Amebiasis is characterized by gastrointestinal and constitutional symptoms and almost always runs a chronic course which is subject to acute exacerbations. The term *amebic dysentery* is properly applied only to the severe cases in which there is diarrhea with blood and mucus in the stools. The term *acute amebic dysentery* is often applied to the acute exacerbations but truly acute cases are probably rare. They are the result of heavy infections such as may occur in epidemics due to contamination of water supplies with sewage.

**Etiology and Pathogenesis** The parasite has two phases trophozoite and cyst. The active trophozoites which are present in infected tissues cause the pathological changes and the cysts which develop from trophozoites on the surface of the mucosa of the colon are responsible for the transmission of the disease. The trophozoites are 10 to 40  $\mu$  in diameter. They exhibit progressive flowing motility and have a nucleus with uniform distribution of peripheral chromatin and a delicate usually centrally placed nucleolus. Some show ingested erythrocytes. Cysts are from 5 to 20  $\mu$  in diameter and contain one to four nuclei similar to those of the trophozoites as well as chromatoid bodies with blunt rounded ends. They have a well-defined wall and are resistant to freezing and partial drying but not to boiling or complete drying.

When cysts are swallowed they pass to the cecum. There by a process called excystation several trophozoites emerge from each cyst and attack and invade the tissues of the colon. The presence of the intestinal bacteria is essential to the production of the intestinal lesions.

**Incidence and Epidemiology** Amebiasis is by no means limited to the tropics but is world wide in distribution and is found as far north as the Arctic Circle. Amebiasis is more prevalent and more severe in the tropics however it may produce severe and even fatal illness in persons who have lived only in the temperate zones. It is more prevalent in areas

where sanitation is poor. In areas devoid of any sanitary facilities rates of infection are often more than 50 per cent. In the United States as a whole Craig has estimated that 10 per cent of the population is infected.

Amebiasis may occur at any age. In unsanitary areas children tend to show the same rates as adults once they have passed the age of five years. In areas of good sanitation children show a much lower incidence than adults. Infection rates are little influenced by sex but 85 to 90 per cent of amebic liver abscesses occur in adult males. Children rarely develop this complication.

Infection takes place when the cysts are ingested. This usually results from fecal contamination of food or drink. Water is contaminated by sewage. Food may be contaminated by being fertilized with human excreta or by flies exposed previously to infected excrement or by food handlers who are careless in their habits. The last method is responsible for the endemicity of amebiasis in places with well protected water and food supplies. Children may infect themselves when playing in soil contaminated with feces. Infection by close personal contact occurs in institutions for mental illness when fecal contamination of the environment plus uncontrollable personal habits are combined.

Epidemics of amebiasis occur occasionally. Perhaps the most famous is that which occurred in Chicago in 1933 when there were more than 1400 cases and more than 100 deaths. Epidemics are usually the result of direct contamination of the water supply with sewage due to faulty plumbing.

**Morbid Anatomy** Amebiasis is characterized by ulceration of the colon which varies greatly in extent and intensity. In fatal cases ulcers may be present throughout the colon and occasionally extend to the terminal ileum. When the process is focal the lesions are most often concentrated in the cecum and ascending colon. The second most frequent localization is in the rectosigmoid area. The larger ulcers penetrate to the submucosa and extend laterally assuming a flask shape. Liver abscess results from the coalescence of focal areas of necrosis. The contents are typically reddish brown in color and the wall is ragged. The affected tissues usually show little cellular reaction in amebiasis.

**Clinical Manifestations** The symptoms of amebiasis vary greatly from patient to patient both with respect to severity and to the presence or absence of specific complaints. They may also vary in severity in the same patient and there may be intervals of relatively good health. The classic

dysenteric form with cramps diarrhea and bloody mucoid stools is seen in only a small proportion of cases at least in the temperate zones. Patients with severe dysentery usually have a history of preceding milder gastrointestinal disturbances although this may be brought out only on careful questioning.

Many infected persons have no complaints. They may be called "carriers" in the sense that they constitute a source of infection for others. In the biological sense however the term carrier does not apply since they often have pathological changes in the colon and may develop clinical manifestations including liver abscess at any time. Sometimes following treatment the so-called carrier will recognize that he has really been having symptoms which were so mild that he was not aware of them. The insidious character of mild amebiasis is striking. The symptoms are often vague and may be peculiarly described by the patient. Consequently a functional disturbance may be suspected especially since the blood count erythrocyte sedimentation rate and other routine studies are usually normal in mild infections. Patients with amebiasis are not infrequently treated for spastic colon or referred for psychiatric advice.

*Diarrhea is a common but by no means constant symptom.* About one third of patients do not have it. The diarrhea may be persistent or intermittent mild or severe. In some instances it is so mild that it is not noticed by the patient. It may alternate with constipation and in some instances the latter is the more prominent symptom. When there is diarrhea stools vary from slightly loose to watery. They sometimes contain mucus and less frequently blood. Other common gastrointestinal symptoms are abdominal distress distention abdominal pain and tenesmus. Vomiting is unusual but nausea occurs in some cases. *Abdominal pain* may be generalized or localized. When it is localized it is often felt in the right lower quadrant owing to involvement of the cecum. In such instances appendicitis may be suspected and a normal appendix is sometimes removed before the correct diagnosis is made. True amebic appendicitis occurs but it is rare.

Constitutional symptoms often accompany the gastrointestinal manifestations and may overshadow them. They include undue fatigue fever which is most often not high vague somatic aching backache and arthralgias. Rarely actual arthritis suggesting the rheumatoid form is seen. There

may also be nervousness irritability or dizziness suggesting a neuropsychiatric disorder. Weight loss is not characteristic. It may occur in relatively severe cases but is rare in mild cases. Patients with pronounced diarrhea may maintain a normal weight and are sometimes actually obese. Anemia is rare in mild cases but frequent when manifestations are severe.

Patients with uncomplicated amebic colitis may have tenderness over the cecum or other portions of the colon. Otherwise physical signs are usually absent unless a very severe dysentery occurs. In such cases the patient shows varying degrees of emaciation and dehydration.

Sigmoidoscopic examination is most often negative in amebiasis. In hospital practice it is not unusual to find ulcerations or other abnormalities in one third or more of cases in office practice however at least in the temperate zone less than 5 per cent of those infected show visible changes. The most typical finding is the presence of ulcers of an irregular shape set in an otherwise normal mucosa. In some cases there is a friable hemorrhagic mucosa suggesting nonspecific ulcerative colitis. It is probably due to secondary bacterial infection.

Roentgenographic examination of the colon is usually negative but in a substantial minority of patients abnormalities are detected. Most often these are observed in the cecum which is irregular narrowed and altered in shape due to edema and spasm. Spasm may occur in other portions of the colon.

Both sigmoidoscopic and roentgenographic examinations are advisable in amebiasis. They give some indication as to the extent of the disease may help in evaluating cure and may detect coexisting but unrelated conditions such as neoplastic disease.

**Complications.** Abscess of the liver is the most common serious complication of amebiasis. It may occur in patients with no previous history of intestinal disorder. There is usually only one abscess and in a large majority of cases it occurs in the right lobe. While the onset of symptoms may be acute it is usually insidious and the diagnosis is frequently difficult. The initial symptom may be unexplained fever. Pain over the liver may not occur until several weeks have passed. The pain may be felt in the upper abdomen or right lower chest and may be referred to the right shoulder or scapular area. Anorexia and weight loss are frequent. Nausea may

occur but vomiting is rare. The fever is usually moderate in degree. It may be associated with sweats.

The physical signs depend on the direction in which the liver enlarges. When the enlargement is chiefly upward, dullness and diminished breath sounds may be noted at the right lung base, simulating pneumonia. If the enlargement is downward, it can be detected by palpation. In either case, there is tenderness over the liver edge and pain on percussion over the liver area. Roentgenographic examination of the chest may show elevation and fixation of the right diaphragm or merely impairment of its excursion. In some cases, there is a localized bulge in its contour. Pleural effusion is present in some instances. The blood shows a moderate increase in the leukocyte count, most often not exceeding 20,000 per cu. mm., with a moderate increase in the percentage of neutrophils, usually only to 75 or 80 per cent. Anemia is frequent. Marked leukocytosis and high fever are usually associated either with a perforated abscess or with secondary bacterial infection. Perforation is not unusual, since the diagnosis may be overlooked for weeks or months. Most often, the abscess perforates into the subphrenic space, right pleural cavity, or right lung. Less often, perforation occurs into other organs adjacent to the liver or into the peritoneal cavity.

There may be less profound involvement of the liver with manifestations indicating recurrent acute hepatitis or low grade chronic hepatitis. In these cases, jaundice is rare, but one or more of the tests of liver function frequently show an abnormal result. The liver may or may not be enlarged to palpation. Tenderness over the liver is often, but not invariably, present. Symptoms suggesting chronic hepatitis are right upper quadrant pain, nausea, variable appetite, and intolerance to alcoholic beverages.

*Pulmonary abscess* is usually the result of extension from a liver abscess, occasionally it occurs independently as an isolated phenomenon. Other rare complications are brain abscess and involvement of the skin, usually in contiguity with internal infection that is adjacent to the rectum, a colostomy, or the drainage tract of a liver abscess. In the colon, major complications are very unusual. They include perforation, stenosis, and a localized productive inflammation called ameboma, which produces the clinical manifestations of a tumor.

**Diagnosis.** Amebiasis should be suspected

in patients with ill-defined gastrointestinal complaints as well as those with diarrhea in patients with unexplained constitutional symptoms and in patients with amebic hepatitis. Periodic routine examination of the stools for *E. histolytica* is advisable in persons exposed to unsanitary conditions.

The diagnosis of intestinal amebiasis is only exceptionally justified without the demonstration of *E. histolytica* in the stools. The identification of *E. histolytica* can be correctly made only by technicians who have had several months of specialized practical training in protozoological diagnosis. The parasite is most readily found in diarrheal stools so that if diarrhea is not present, it should be produced by the administration of a saline cathartic. These diarrheal stools must be examined promptly using warm slides and saline in order that the characteristic motility of the trophozoites may be observed.

In diarrheal stools, it is usual to find only trophozoites. Cysts may occur but are more frequently found in formed stools. In many patients, cyst formation is a variable process so that for periods as long as several weeks, it may be impossible to detect them. Hence, reliance on casual formed specimens greatly reduces the likelihood of a positive finding.

Cultures have only a limited value in the diagnosis of amebiasis, for in many cases, the amebas do not grow readily. In selected cases, the method is a useful adjunct to the direct examination of fresh stools. Iron-hematoxylin stained preparations are useful for permanent records but are too time-consuming for routine use.

As lesions are frequently present only in the upper colon, specimens obtained through the sigmoidoscope are of limited value; they are most likely to yield positive results when visible lesions are present. Great care must be exercised not to mix the leukocytes frequently present in mucus with amebas.

The administration of antimicrobials such as the sulfonamides or the tetracyclines before the stool specimens are obtained greatly increases the difficulty of finding *E. histolytica*. Hence, the empirical treatment of diarrheas with these agents is not advisable. The presence of mineral oil and barium in the intestinal tract temporarily interferes with the detection of amebas.

When there are manifestations suggestive of amebic abscess of the liver, the demonstration of *E. histolytica* in the stools helps to confirm the diagnosis. In some

cases it is not possible to find the parasite. This is true especially if antimicrobials have been given empirically because the patient has had an unexplained fever. The specific complement fixation reaction is of considerable value since it appears to be positive in all cases of liver abscess due to *E. histolytica*. In patients with hepatitis but no abscess the reaction may be either positive or negative. The test is negative in the large majority of cases of uncomplicated intestinal amebiasis. In cases in which the reaction is positive it may remain so for many months after cure. Unfortunately the results reported on a research basis cannot be consistently obtained in the routine diagnostic laboratory probably because of the technical difficulty of producing a satisfactory antigen.

Further corroborative evidence for the diagnosis of amebic abscess is the response to specific therapy. In uncomplicated amebic abscess there is almost always prompt and dramatic abatement of symptoms within twenty-four to forty-eight hours after emetine is started. The response to chloroquine is less dramatic.

Some patients are so seriously ill that there may not be time to carry out proper stool examinations and therapeutic tests. In these cases it may be necessary to perform an exploratory laparotomy because the diagnosis is obscure and an acute surgical condition is suspected. If in the course of such an operation an abscess of the liver is encountered it should be aspirated and specific therapy for amebiasis instituted immediately pending laboratory examination of the material obtained. In the absence of some other obvious infection, liver abscess is almost always amebic. If the aspirated material is brown in color one can be almost certain of the diagnosis even though it does not usually contain demonstrable *E. histolytica*. However, if open drainage has been instituted and inadvertently no emetine or chloroquine has been given, the parasites can sometimes be found in the discharge after several days since the material now comes from the ameba-containing abscess wall.

The aspirate should be cultured for bacteria. A negative result supports the diagnosis of amebic abscess. A positive result indicates either secondary infection of such an abscess or a nonamebic abscess.

**Prognosis.** Many cases of mild amebic colitis respond rapidly and completely to a single course of an oral amebicide. A few prove more resistant. In general the more severe the manifestations the more likely

the case is to be resistant to cure. In acute hepatitis and liver abscess the prognosis as to cure is excellent. Low-grade hepatitis often requires prolonged treatment and may be difficult to clear up permanently and completely. Death from amebiasis occurs only when the disease goes unrecognized or occasionally in patients weakened by other illness or subjected to massive amebic infection. A fatal outcome is most often due to liver abscess or its complications.

In those cases of amebiasis in which cure is not accomplished the patient can be kept in reasonably good health with periodic specific treatment. Reasonable criteria of cure are freedom from clinical manifestations for one year together with postcathartic stool specimens which are repeatedly negative for *E. histolytica*. Stool specimens should be examined on approximately six different occasions at increasing intervals over the period of one year following the completion of therapy.

**Treatment.** In severe amebic colitis characterized by marked diarrhea usually with blood in the stools and fever, treatment should be started with emetine hydrochloride 1.0 mg per kg of body weight (maximum 0.065 gm) administered daily by deep intramuscular injection. On the first day it should be divided into two doses so that any idiosyncrasy may be detected. The emetine should be continued only long enough to control the severe symptoms but not for more than five days in order to avoid serious toxic effects on the heart. Emetine should be followed by five days of antibacterial therapy either a combination of sulfasuxidine 1.0 gm four times a day and penicillin 500,000 units intramuscularly once a day, or one of the tetracyclines by mouth 0.25 gm four times a day. Then diiodohydroxyquinoline (Diodoquin) 0.65 gm four times a day is given for twenty days. Finally one to two weeks after termination of this regimen either carbarsone 0.25 gm three times a day for 10 days or fumagillin (Fumidil) 10 mg three times a day for ten days should be prescribed.

If the patient has moderate diarrhea and no fever, emetine is omitted. In mild or asymptomatic amebiasis no antibacterial therapy is necessary and it is usually sufficient to give a single treatment with Diodoquin, carbarsone or fumagillin in the doses mentioned above. Diodoquin is preferred because of the low incidence of untoward effects, none of which is serious. Carbarsone often produces gastrointestinal dis-

turbances less often skin eruptions and rarely jaundice. Fumagillin not infrequently produces marked gastrointestinal irritation it may possibly cause neutropenia.

A considerable number of other drugs have been and are used as oral amebicides. None has any distinct advantage over those already discussed. Some are less effective others are more prone to produce adverse effects. In any individual case however a statistically less effective drug may prove effective when a more standard drug has failed. The more important alternative amebicides are

#### Iodine Quinoline Compounds

Vioform 0.25 gm 3 times a day for 10 days

Chiniofon 1.0 gm 3 times a day for 10 days

(Anayodin)

#### Arsenical

Milhibis (bismuth glycoarsanilate)

Oral Antimicrobials 0.5 gm 3 times a day for 8 days

Chlortetracycline 0.5 gm 4 times a day for 2 days or more followed by 0.25 gm 4 times a day for the balance of 7 days

Oxytetracycline 0.5 gm 4 times a day for 7 days

Bacitracin 20 000 units 4 times a day for 10 days

Chiniofon was the precursor of Diodoquin. It is little used now because it is less effective and frequently causes diarrhea which prevents administration of an adequate dose. Vioform even at a dose of 0.5 gm three times a day twice the standard dose is less effective than Diodoquin. Milhibis is no more effective than carbarsone and has similar drawbacks. The tetracyclines probably act indirectly by depressing the intestinal bacteria upon which *E. histolytica* depends for some essential factor or factors. The tetracyclines are almost as effective as Diodoquin in mild amebiasis but are apt to produce marked gastrointestinal symptoms which may be more troublesome than those of mild amebiasis. Bacitracin is less effective than the tetracyclines but is relatively free of side effects.

Amebic liver abscess and acute amebic hepatitis are treated with chloroquine (Aralen) diphosphate rather than emetine since adequate doses of the latter may have serious toxic effects on the heart. The dose is 0.25 gm three times a day for two weeks. Visual disturbances due to chloroquine may be ignored if there is marked nausea or dizziness or severe insomnia the dose is reduced to 0.25 gm twice a day and treatment is prolonged so that the total dose is still 10 to 11 gm. If emetine is used because chloroquine has not been effective or cannot be obtained the dose is 1.0 mg per kg of body weight

(maximum 0.065 gm) once a day for ten days. The pulse and blood pressure should be checked before each injection. If there is a pronounced fall of blood pressure or rise in pulse rate the treatment should be stopped. The patient's activity should be markedly restricted not only during therapy but for four weeks thereafter since emetine is slowly excreted.

Specific therapy will cure a majority of patients with liver abscess. If there is persistent fever or other evidence of incomplete resolution of the abscess drainage by aspiration or open operation is indicated.

In chronic amebic hepatitis the dose of chloroquine should be 0.25 gm twice a day since these patients seem to tolerate it less well than those with acute involvement. A total dose of 10 gm should be used. In addition the general measures used in other chronic hepatic disease are indicated. All patients with amebic liver disease should be treated for intestinal involvement as well even if there are no symptoms of colitis. Neither emetine nor chloroquine can be relied upon to clear up the intestinal infection.

**Prevention.** Ordinary concentrations of chlorine including those produced by Halaron tablets cannot be relied upon to kill amebic cysts. For small scale use a tablet containing tetraglycine hydropeniodide (Globaline) which liberates iodine is effective against amebic cysts as well as common water borne bacterial infections. For public water supplies the addition of proper filtration to chlorination is effective. Other preventive measures are sanitary disposal of feces, avoidance of use of human excreta for fertilization, fly control and detection and treatment of mild or asymptomatic infections especially in food handlers.

## Coccidiosis

**Etiology** Coccidiosis is an infection caused by sporozoan parasites belonging to the genus *Isospora*. Only a few hundred infections of man with *Isospora* have been reported but the infection is undoubtedly more common in many countries with poor sanitary conditions than published reports would indicate. Surveys in Brazil and Egypt demonstrated *Isospora* oocysts in approximately 0.1 per cent of the stools examined. The majority of reported infections have been among British soldiers serving in the Middle East but the infection is world wide. Infections originating in Africa, China, Japan, India, the Philippines, Indonesia, Hawaii, South America and North America have been reported. Magath found only one infection in 60,000 patients examined at the Mayo Clinic. Many of these patients were from foreign countries. *I. bigemina* found commonly in the dog appears to be indistinguishable from *I. hominis* and may be a source of human infection.

**Ingestion of oocysts of species of Eimeria** parasitic in the liver of herrings in the testes of sardines and in the liver of rabbits may lead to erroneous diagnosis. These "foreign" coccidians pass through man's alimentary tract intact and are examples of pseudo parasitism.

**Morbid Anatomy** The life cycle and pathology of *Isospora* infections in man have been inadequately studied because limited postmortem material has been available. The schizogonic phase of the cycle probably occurs in the epithelial cells of the lower portion of the ileum. The encysted fertilized eggs (oocysts) pass down the bowel and out in the feces. In *I. belli* infections oocysts 30 by 12  $\mu$  are passed in the feces. They are in early stages of development; the mature oocyst contains two sporocysts each with its four sporozoites. *I. hominis* is usually passed fully

developed; the oocyst wall is usually absent and the sporocysts containing four sporozoites may be single or coupled in pairs each being 15 by 10  $\mu$ . The sporocyst or oocyst containing two sporocysts with their eight sporozoites are ingested with feces contaminated food or drink hatch in the small intestine and initiate a new infection.

**Clinical Manifestations** Experimental infections in human volunteers have demonstrated the pathogenicity of *Isospora*. Diarrhea begins one week after the ingestion of the oocysts and persists for one to four weeks. The stools are liquid, brownish yellow in color, contain a large amount of undigested material and fat, and Charcot-Leyden crystals are often present. Fever, abdominal pain, nausea and vomiting of varying degrees accompany the diarrhea. Typical oocysts appear in the stool after two to four weeks and persist for approximately a month. The eosinophile count was essentially normal in the experimental infections. It has been reported to be increased in a number of patients with natural infections in whom, however, *Schistosoma* hookworm or *E. histolytica* were also present. Clinical observation of patients during a period of several months indicates that the infection may be present without the production of significant signs or symptoms. Infections with *Isospora* appear to be self limited and last only a few weeks unless there is repeated oral reinfection. In the treatment of coccidiosis there is no specific therapy available although a number of compounds have been used with considerable success in the coccidiosis of domestic animals.

**Prevention** The prevention of coccidiosis consists of avoiding water and food which may be contaminated with *Isospora* oocysts. Thorough cooking of food and boiling of water will prevent infections when in endemic areas.

## Malaria

**Definition** Malaria is an infectious febrile disease produced by several species of protozoa belonging to the single genus *Plasmodium*. It is transmitted naturally from host to host only by the bite of an infected *Anopheles* mosquito. In the mosquito the development of the parasite is observed on the stomach wall and in the salivary glands while in man it is continued in the erythrocytes. Clinically the disease is characterized by paroxysms of severe chills, fever, and sweating. These paroxysms may occur daily (quotidian) on alternate days (tertian) or with an interval of three days between chills (quartan). After recovery from the acute attack the disease has a tendency to become chronic with occasional relapses.

**History** Some of the earliest records of man show that malaria was recognized as a definite clinical entity. In the fifth century B.C. Hippocrates differentiated the fever into quotidian, tertian, and quartan types. In 1680 a French army surgeon by the name of Laveran recognized the pigmented parasites in the erythrocytes of a soldier in Algiers and was convinced that they were the cause of malaria. Soon all the different asexual stages of the parasites were recognized in the erythrocytes. In 1897 MacCallum saw the fertilization of a female gametocyte following the exflagellation of a male gamete and correctly assumed that the malaria parasite had a sexual and an asexual cycle. The incrimination of the mosquito as the vector for malaria followed the work of Theobald Smith who was the first to discover the arthropod transmission of disease when the tick was shown to be the essential intermediate host in Texas cattle fever. English and Italian workers quickly applied the same principle to malaria and found that certain *Anopheles* mosquitoes were infected and responsible for the transmission in man. By 1900 the details of the cycle in man and mosquito were known and the highly specialized manner by which this disease propagates itself was understood. This complete information in addition to the long known efficacy of quinine as a treatment led many to believe that malaria would soon be eradicated but almost 60 years later this belief remains far from realization.

**Epidemiology** Malaria at the present time is one of humanity's chief scourges and there are many fertile areas that remain uninhabitable because of its influence. On the other hand the disease has been eliminated from many areas and currently the World Health Organization has undertaken a world wide program. In the United States indigenous malaria has practically disappeared.

**Malaria in World War II** The introduction of American troops in World War II into South Pacific areas, Africa, Middle East, China, Burma, and India resulted in thousands of malarial infections. Malaria

soon became the outstanding medical problem of the war not from the standpoint of mortality because there were relatively few deaths but because of the high degree of morbidity. The most disturbing feature was the great number of *vivax* relapses which occurred at periodic intervals usually every four to six weeks. For several years after World War II and the Korean conflict there was a considerable residue of men with relapsing infections. Some of these patients experienced as many as forty or more distinct episodes.

The malaria acquired overseas was both the *falciparum* and the *vivax* variety. As the former has an extremely low relapse rate practically all malaria seen in the United States is the less severe and more persistent *vivax* form. A noticeable feature of the malaria seen in the returning service man is the absence of malarial cachexia so prevalent in populations native to endemic areas. Enlarged spleens, anemia, and other commonly associated debilities are not frequently encountered even in servicemen with a long history of malaria. This suggests that cachexia develops only when malaria is associated with other infections or poor nutritional states.

**Etiology** The specific etiologic agent of malaria is a unicellular organism which lives at the expense of the erythrocytes in certain reptiles, birds, and mammals and belongs to the order of Hemosporidia, class Sporozoa, and the single genus *Plasmodium*. The species within the genus are not numerous and they are capable of producing infections only in hosts that are closely related. In man malaria is produced by four specific parasites known as *Plasmodium vivax*, *P. malariae*, *P. falciparum*, and *P. ovale*. There are certain similarities among these parasites but each has a distinct morphology and definite pathogenicity and none of them has been found infectious for any of the lower animals. Unlike viral or bacterial diseases the etiologic agent of malaria has not been successfully cultivated on an artificial medium or in the presence of living cells outside its respective host. The only means of transmission in nature is by *Anopheles* mosquitoes although different species act as vectors in different parts of the world. The *Anopheles* mosquito does not act as a mere mechanical transmitter of the pathogen from man to man but serves as a haven where the parasite undergoes a definite development necessary for the perpetuation of the organism. An artificial method of transmission is the hypodermic

syringe commonly used by drug addicts which results in the actual transfer of infected blood from a carrier to a susceptible person. This type which occurs more often in the larger cities is responsible for many deaths since it is usually the highly virulent falciparum malaria. Less frequently malaria is acquired in nonendemic areas after transfusions from an infected donor. There are many authenticated reports of children becoming infected from parent donors who last had symptoms twenty or more years previously. It is interesting to note that in practically all such instances the causative agent has been *P. malariae*.

**The Mosquito Host.** Many different species of anopheline mosquitoes have been described from various parts of the world. Although most of them can transmit malaria, they vary enormously in their susceptibility. In North America *Anopheles quadrimaculatus* has been shown to be the only important vector. The habitat of this mosquito extends to the southern border of Canada, but the severe winters in addition to agricultural drainage and clearing have largely limited its activity as a disease carrier to the southern states. The adult anopheline mosquito is identified by its spotted wings and its habit of resting at an angle. Only the female mosquito can become infected since she requires a blood meal to produce fertile eggs. The male is not bloodsucking. Anopheline mosquitoes lay their eggs in swamps, ponds, and streams; the larvae lie and feed horizontally on the surface of the water, a characteristic which makes them more liable to destruction by floating larvae-eaters, particularly oids and Paris green. The common pest mosquito *Culex* lays its eggs in eaves, tin cans, cisterns, or any container of water in and about houses. The larvae hang head downward with an air siphon sucking above the surface of the water; the body of the adult is parallel to the surface of its resting place. It is not concerned with the transmission of malaria and is definitely a domestic mosquito, while the anopheline prefers a wilder environment.

**Development of the Malaria Parasite in the Mosquito.** In order to become infected a female mosquito must first bite a person who has male and female malaria parasites in the circulating blood, since the asexual parasites cannot survive in the mosquito's stomach. The sexual form, known as gametocytes, initiate the cycle of development within the stomach of the mosquito, where they undergo fertilization. This is accomplished by the male parasite pushing out several flagella which break loose and come into contact with the female form. Many attempt to penetrate, but when one succeeds the foiled ones depart for other quarry. (This also can be observed readily under the darkfield microscope.) The fertilized forms then push their way out between the stomach cells and form cysts on its outer wall. These cysts, known as oocysts, gradually enlarge so that by the eighth or tenth day they are mature and measure about 75  $\mu$  in diameter. If examined under the microscope the oocysts will be seen to be distended with spindle-shaped sporozoites. At this time they rupture into the body cavity of the mosquito and the liberated sporozoites make their way to the salivary glands, where they lie and await an opportunity to enter the blood stream of a susceptible person. The sporozoites escape from the salivary glands as the infected mosquito bites

a person, thus initiating the cycle of development in the human host. At this step there is a missing link in the life history of the malaria parasite: it was last seen as a spindle-shaped sporozoite in the salivary gland of the mosquito and next observed about ten days later as a "ring-shaped" parasite in the human erythrocytes. No one has recognized an intermediary form or understood the exact manner in which it attacks the erythrocytes.

**Malaria Parasites in Man.** The most common variety is *Plasmodium vivax*. About ten days after an infection has been acquired through the bite of an infected anopheline, the first parasites are observed in the erythrocytes as circles of cytoplasm with a mass of red chromatin. This stage is commonly referred to as the "ring form." There follows a progressive growth of the parasite into an ameboid stage characterized by irregular arrangement of the cytoplasm, appearance of pigment granules, and enlargement of the chromatin. The infected erythrocyte becomes somewhat larger and paler than normal and contains numerous reddish granules known as Schuffner's dots which occur only with this species of parasite. As the parasite continues to enlarge the amount of pigment increases and the nucleus starts to divide. At the end of forty-eight hours the erythrocyte is a mere membrane; all hemoglobin has been devoured or replaced by the parasite. The nuclear fragments have assumed a "rosette" form and each unit is known as a merozoite, which is a daughter parasite. As the erythrocyte ruptures, the cluster of merozoites, usually 16 in number, are released and each attaches itself to a new cell. The cycle is then repeated every forty-eight hours, but fortunately for man not every merozoite that is released finds its way unhindered to reproduce its full quota of progeny. Fully 90 per cent of the merozoites are destroyed by the macrophages located chiefly in the spleen, liver, and bone marrow. For some unknown reason there is a tendency for the vivax merozoite to prefer a reticulocyte to a mature erythrocyte for initiating its development.

The asexual reproduction of the parasite continues for several days when new forms appear, the sexual ones (gametocytes). They fill the entire erythrocyte. Their pigment is scattered and chromatin is diffuse. The male parasite may be differentiated from the female by its pale staining cytoplasm with Giemsa or other Romanowsky stains. The gametocytes are concerned only with infection in the mosquito; have no clinical importance and usually persist in the blood in limited numbers for two or three weeks. The characteristics which dif-

## Malaria

**Definition** Malaria is an infectious febrile disease produced by several species of protozoa belonging to the single genus *plasmodium*. It is transmitted naturally from host to host only by the bite of an infected anopheline mosquito. In the mosquito the development of the parasite is observed on the stomach wall and in the salivary glands while in man it is continued in the erythrocytes. Clinically the disease is characterized by paroxysms of severe chills, fever and sweating. These paroxysms may occur daily (quotidian) on alternate days (tertian) or with an interval of three days between chills (quartan). After recovery from the acute attack the disease has a tendency to become chronic with occasional relapses.

For several years after World War II and the Korean conflict there was a considerable residue of men with relapsing infections. Some of these patients experienced as many as forty or more distinct episodes.

The malaria acquired overseas was both the falciparum and the vivax variety. As the former has an extremely low relapse rate practically all malaria seen in the United States is the less severe and more persistent vivax form. A noticeable feature of the malaria seen in the returning service man is the absence of malarial cachexia so prevalent in populations native to endemic areas. Enlarged spleens, anemia and other commonly associated debilities are not frequently encountered even in servicemen with a long history of malaria. This suggests that cachexia develops only when malaria is associated with other infections or poor nutritional states.

**Etiology** The specific etiological agent of malaria is a unicellular organism which lives at the expense of the erythrocytes in certain reptiles, birds and mammals and belongs to the order of Hemosporidia class Sporozoa and the single genus *Plasmodium*. The species within the genus are not numerous and they are capable of producing infections only in hosts that are closely related. In man malaria is produced by four specific parasites known as *Plasmodium vivax*, *P. malariae*, *P. falciparum* and *P. ovale*. There are certain similarities among these parasites but each has a distinct morphology and definite pathogenicity and none of them has been found infectious for any of the lower animals. Unlike viral or bacterial diseases the etiological agent of malaria has not been successfully cultivated on an artificial medium or in the presence of living cells outside its respective host. The only means of transmission in nature is by anopheline mosquitoes although different species act as vectors in different parts of the world. The anopheline mosquito does not act as a mere mechanical transmitter of the pathogen from man to man but serves as a haven where the parasite undergoes a definite development necessary for the perpetuation of the organism. An artificial method of transmission is the hypodermic

classic features according to the species involved

**Vivax or Tertian Malaria** This is by far the most common the mildest and most likely to recur Because large numbers of persons have received the beneficial effects of vivax malaria in the treatment of neurosyphilis excellent opportunities have been afforded for observing the symptoms of vivax infections in great detail The most thoroughly studied malaria infections were induced by the bite of infected mosquitoes and once established they were allowed to run their full course in order to obtain greatest therapeutic results In a typical infection about six days after the bite of the mosquito the patient has a mild backache muscle soreness and a low grade fever without chills Febrile paroxysms appear about the fourteenth day Usually these paroxysms occur on alternate days and coincide with the segmentation of the mature parasite They may occur daily (quotidian) however which means that there are two broods of the same parasite one segmenting on even days and the other on odd days of the disease or the two types may occur during the course of the one infection as shown in Figure 40 A typical paroxysm for vivax malaria consists of "cold" "hot" and "sweating" stages

**COLD STAGE** The patient has a chilly sensation over the entire body which gradually increases in intensity the teeth chatter the skin becomes blue and cold and there is an uncontrollable shaking In spite of heat pads and blankets it is impossible to keep the patient warm The pulse is rapid and weak and occasionally there are nausea and vomiting The cold stage lasts on the average one hour and subsides as the body temperature rises

**HOT STAGE** In this stage the patient has a flushed face and severe headache and may be partially delirious with a tempera-

ture often as high as 107° F There is a sensation of intense heat with a hot dry skin This portion of the paroxysm lasts about two hours

**SWEATING STAGE** The sweating stage has an abrupt onset and the patient breaks out into a profuse perspiration Temperature drops to normal the headache disappears and a feeling of well being comes over the patient Although somewhat drowsy and weak he feels able to resume work

**Quartan Malaria** This parasite produces an infection (after a prolonged incubation period) which may vary from eighteen to forty days The onset is similar to that of vivax malaria being initiated by a low grade remittent fever lasting three to five days without chills The paroxysms usually occur every seventy-two hours the time required for the complete development of the asexual cycle in the blood However the total period from the beginning of the day of one chill to the end of the day of the next paroxysm is four days (Fig 11) which accounts for the unfortunate name quartan malaria A double quartan infection produces a chill on two consecutive days with an intervening day of normal temperature Rarely does one encounter daily chills with quartan malaria When compared with vivax malaria the paroxysm lasts longer is slightly more severe and the patient feels less like leaving his bed between chills

**Falciparum Malaria** Falciparum or estivoautumnal malaria is a more severe disease than the others and as such is responsible for the origin of the purely descriptive terms of the disease as cerebral algid hemorrhagic pernicious and many others The latter refer to symptoms which depend largely upon the localization of the parasites The incubation period is commonly twelve days the fever is irregular and not characteristic The paroxysms are similar

FIG 40 Temperature chart of a patient with vivax malaria showing both tertian and quotidian types of fever (Photograph by J B Haulenbeck)

ferentiate *P. vivax* from other parasites are a forty-eight hour cycle 16 merozoites in the mature parasite at time of segmentation and an enlarged pale parasitized erythrocyte usually stippled with red staining granules

*Plasmodium malariae* which produces quartan malaria in man requires seventy two hours to complete each asexual cycle in the erythrocyte Except for its slower metabolic activity this parasite bears a close similarity to the behavior of *P. vivax* Morphologically the young parasite is frequently observed as a band form across the cell The parasitized erythrocyte seems to have a greater concentration of hemoglobin and is somewhat reduced in size There are usually only eight merozoites in the mature parasite and after segmentation they prefer to attach themselves to mature erythrocytes rather than the younger reticulocytes

The asexual cycle of *Plasmodium falciparum* is first recognized as an extremely small "signet ring" in the erythrocyte approximately one half the size of a *P. vivax* ring Only in the severest cases are the more mature stages of the parasite seen in the erythrocyte The reason for this seems to be that early in the acute infection there is a tendency for the ring forms to aggregate in the capillaries throughout the body where they undergo their usual development The required time for one cycle is not definitely known but is probably between twenty four and forty-eight hours The gametocytes are crescent shaped a definite diagnostic finding since no other known malaria parasite has this morphology The parasite seems to attack young and old erythrocytes indiscriminately

*Plasmodium ovale* first described in 1923 by Stephens and now generally accepted as a definite species derived its name from the fact that the infected erythrocyte always assumes an oval shape Otherwise its morphology and behavior are practically identical with those of *P. vivax*

**Morbid Anatomy** Patients with tertian or quartan malaria rarely come to autopsy except when the malaria is a contributory cause of death The pathological lesions in these instances are in the main due to the disintegration of parasitized erythrocytes and the accumulation of pigment The maximum evidence of an active or latent malarial infection is found in the spleen and because of the collection of pigment no other disease presents a more pronounced pathognomonic picture either macroscopically or microscopically The

spleen is usually markedly enlarged slate gray in color and of soft consistency during the acute disease The capsule is smooth and tense and may even rupture spontaneously The cut surface exudes a brownish pulp and the malpighian bodies stand out Microscopically the sinuses are distended with parasitized and normal erythrocytes The macrophages are laden with parasitic debris which is mostly pigment The liver is usually somewhat enlarged and slightly darker than normal Microscopic examination reveals that the kupffer cells are engorged with parasites in various stages of disintegration There is little or no evidence of toxic degeneration in the parenchymal cells The heart lungs kidneys and pancreas have a normal cellular structure and the only finding of interest is again the presence of pigment in the active macrophages

Falciparum malaria is responsible for the majority of deaths due to uncomplicated malaria and likewise presents some pathological lesions not present in *vivax* or quartan malaria Fatal cases are usually associated with an overwhelming infection and cerebral involvement The brain shows a gross brownish discoloration of the gray matter with macroscopic punctuate hemorrhages in the white matter Stained sections reveal the capillaries filled with parasites in various stages of development The cerebral capillary occlusion which is characteristic of falciparum malaria may also frequently be generalized and present a pathological picture of congestion A pathologist is frequently able to make the correct diagnosis of this disease from a glance at the exposed tissues because of the slate gray tinge due to capillary engorgement with pigmented parasites

**Symptoms** The symptoms of malaria vary according to the type of parasite producing the disease Each of the four parasites has a characteristic behavior and time of sporulation which give rise to different clinical pictures Symptoms also vary according to host resistance or immunity For example in areas of high malaria endemicity people may go about their work with no apparent difficulty despite the presence of a considerable number of circulating parasites in their blood stream Less intense infections gauged by the number of circulating parasites will completely prostrate a nonimmune person coming into the same area There is evidence to show that strains of the same species of parasite may also have different virulence However the initial infections in susceptible persons have certain

where the patient resides or that he has traveled in infected areas for example campers and hunters frequently acquire malaria in this manner

There are few physical signs The patient appears anemic the degree varying according to the duration and severity of the disease The spleen if sufficiently enlarged to be palpated is soft in the acute disease and firm in chronic cases

A therapeutic diagnostic test is useful if correctly interpreted If a potent anti malarial drug fails to reduce a patient's fever it is strong evidence that the fever is not caused by malaria Likewise it is extremely important that the physician ascertain whether the patient has taken some remedy on his own initiative before seeking medical aid This self medication is a common practice and accounts for a temporary cessation of symptoms and disappearance of parasites from the blood stream

In addition to the diagnosis of the individual case the physician is frequently called upon to determine the prevalence of malaria in a community The established routine procedure is to determine the incidence of parasitemia (by blood smear examination) in as large a group of persons as is feasible At the same time a determination of the number of enlarged spleens and the degree of splenomegaly furnishes additional information Personal history about malarial infections in previous years is also included Such a survey will give data permitting the quantitative expression of the amount of malaria in a community and if continued will furnish a guide to yearly endemicity of the disease

**Prognosis** Patients with vivax or quartan malaria rarely if ever succumb unless the malaria is complicated by other diseases malnutrition or exposure Even in endemic areas where many infections are self treated deaths are few Moreover in paretics in whom malaria has been induced for therapeutic purposes and allowed to run a full course without intervention the death rate is almost nil Vivax and quartan malaria are diseases of high morbidity and low mortality

Falciparum malaria is the cause of practically all deaths due to malaria but if recognized early usually responds to therapy A guarded prognosis must be made for patients with the cerebral type in coma or stupor Malaria with hemoglobinuria always presents a grave prognosis

**Relapses** are to be expected with all types of malaria These may occur at any time but are most likely to occur after exposure

change of climate hemorrhage or when body resistance is lowered from any cause

**Immunity** A malarial infection confers a low grade but specific immunity upon its host after the acute attack has subsided This acquired immunity in man is of short duration and a person may have repeated attacks produced by the same organism within a relatively short space of time In experimental animals the residual immunity following complete eradication of the infection persists only a few weeks Many believe that a host is immune to malaria only in the presence of infection There is no cross immunity in human malaria since it is frequently observed that a person may have a simultaneous infection with two or more types of plasmodia It is highly probable that a person is resistant only to the malaria in his particular locality for example it has been shown that a person immune to a strain of vivax malaria in Florida behaves as a normal when exposed to infection from a vivax parasite from Cuba

The mechanism of immunity in malaria is not clearly understood but it is possible to demonstrate specific protective and complement fixing antibodies and agglutinins in the serum of experimental animals after recovery from the acute attack The chief defense of the body against an acute malarial infection or recovery from a relapse probably depends upon a greatly accelerated rate of phagocytosis by the individual macrophages of the reticuloendothelial system

**Treatment** The accepted treatment for malaria is the administration of certain chemotherapeutic drugs Specific antiserum prepared from animals or serum from convalescent patients has not proved beneficial in the prevention or treatment of the disease

It is now possible to state that satisfactory suppressive and curative compounds for vivax and falciparum malaria are available There have been insufficient tests of these recently introduced compounds in quartan malaria Moreover preliminary studies indicate that certain of the new compounds are probably true prophylactic agents This would be in contrast to the previously available "prophylactic" drugs which did not actually prevent infection but suppressed evidence of disease so long as prophylaxis was continued These goals visualized and sought by malarologists for centuries are now at hand

It is possible to make these statements because of the results of a research program initiated at the beginning of World

FIG 41 Temperature chart of a patient with quartan malaria

to those accompanying other malarials although of longer duration and occurring at more irregular intervals. The temperature is usually high. If there is a cerebral localization of the parasites the onset is rapid with delirium or coma and death frequently ensues without a return to consciousness. The disease may present a gastrointestinal syndrome with abdominal cramps, diarrhea, vomiting, and only a few parasites in the peripheral blood. The patient is markedly dehydrated and may have a high or low grade fever. Stools may contain blood resulting from intestinal capillary thrombosis and ulceration.

**Blackwater Fever.** Blackwater fever, sometimes called hemoglobinuria, is the most serious and frequent complication of malaria but occurs almost entirely in the falciparum variety. The etiology of blackwater fever is not understood. At one time this complication was very prevalent in the United States but it is no longer present there. It now occurs only in certain of the more heavily endemic areas of Africa and the Orient. Blackwater fever does not appear until the patient has had repeated attacks of malaria. The first sign is a pronounced darkening of the urine produced by the hemoglobin released during extensive intravascular hemolysis. The blood pigments very rapidly increase in amount in the urine until there is a copious amorphous deposit. The pulse becomes very rapid, the fever is high, 105° F or more, and curiously enough parasites are usually absent at this stage. The erythrocyte count drops to 2,000,000 cells per cu mm or lower within twenty-four or forty-eight hours, and vomiting and jaundice are likewise early symptoms. The appearance of blackwater fever is associated with a very poor prognosis, the mortality being approximately 50 per cent. The only known treatment is absolute rest. The body fluid should be restored as rapidly as possible, preserv-

ing normal concentrations of protein and salt. Excessive blood transfusions should be avoided since cardiac failure often results.

**Diagnosis.** An absolute diagnosis of malaria depends upon the recognition of the parasite in stained thin or thick blood smears. Ordinary thin smears should be made on slides that have been thoroughly cleaned to ensure even spacing of the erythrocytes. They can be stained with Giemsa's, Wright's or Hastings' stain. For the uninitiated the thin smear method is preferred because there is less opportunity to be confused by artifacts. It is easy to overlook parasites by this method, however, although they may be present in sufficient numbers to produce clinical activity. The thick smear method is advantageous because it affords a means of concentrating the blood. The thick film should be about the size of a dime on a very clean slide. The two preferred methods of staining are Giemsa's and Field's. The former is satisfactory and is accomplished by adding one drop of Giemsa to 1 ml of distilled water and staining for thirty minutes. Field's method has many advantages: long drying of the film is unnecessary, the entire staining takes less than 10 seconds, and there are fewer artifacts. (Consult J. W. Field, *Tr. Roy. Soc. Trop. Med.* 35:35, 1941.) The greatest number of parasites appears in the blood stream immediately after the chill and for the following six hours. The inability to find parasites in blood films does not exclude the presence of malaria, particularly in a subsiding or chronic infection. Splenic puncture for diagnostic purposes is unwarranted and dangerous, since it may lead to the rupture of an enlarged, tense spleen.

The chief complaints of the patient are usually severe chill, high fever, and sweating. In the history there is also usually information showing that malaria is endemic.

where the patient resides or that he has traveled in infected areas for example campers and hunters frequently acquire malaria in this manner

There are few physical signs The patient appears anemic the degree varying according to the duration and severity of the disease The spleen if sufficiently enlarged to be palpated is soft in the acute disease and firm in chronic cases

A therapeutic diagnostic test is useful if correctly interpreted If a potent anti malarial drug fails to reduce a patient's fever it is strong evidence that the fever is not caused by malaria Likewise it is extremely important that the physician ascertain whether the patient has taken some remedy on his own initiative before seeking medical aid This self medication is a common practice and accounts for a temporary cessation of symptoms and disappearance of parasites from the blood stream

In addition to the diagnosis of the individual case the physician is frequently called upon to determine the prevalence of malaria in a community The established routine procedure is to determine the incidence of parasitemia (by blood smear examination) in as large a group of persons as is feasible At the same time a determination of the number of enlarged spleens and the degree of splenomegaly furnishes additional information Personal history about malarial infections in previous years is also included Such a survey will give data permitting the quantitative expression of the amount of malaria in a community and if continued will furnish a guide to yearly endemicity of the disease

**Prognosis** Patients with vivax or quartan malaria rarely if ever succumb unless the malaria is complicated by other diseases malnutrition or exposure Even in endemic areas where many infections are self treated deaths are few Moreover in paretics in whom malaria has been induced for therapeutic purposes and allowed to run a full course without intervention the death rate is almost nil Vivax and quartan malaria are diseases of high morbidity and low mortality

The mechanism of immunity in malaria is not clearly understood but it is possible to demonstrate specific protective and complement fixing antibodies and agglutinins in the serum of experimental animals after recovery from the acute attack The chief defense of the body against an acute malarial infection or recovery from a relapse probably depends upon a greatly accelerated rate of phagocytosis by the individual macrophages of the reticuloendothelial system

**Treatment** The accepted treatment for malaria is the administration of certain chemotherapeutic drugs Specific antiserum prepared from animals or serum from convalescent patients has not proved beneficial in the prevention or treatment of the disease

It is now possible to state that satisfactory suppressive and curative compounds for vivax and falciparum malaria are available There have been insufficient tests of these recently introduced compounds in quartan malaria Moreover preliminary studies indicate that certain of the new compounds are probably true prophylactic agents This would be in contrast to the previously available prophylactic drugs which did not actually prevent infection but suppressed evidence of disease so long as prophylaxis was continued These goals visualized and sought by malarialogists for centuries are now at hand

It is possible to make these statements because of the results of a research program initiated at the beginning of World

War II and continued until the present. Nevertheless, it would be incorrect to assume that no problems continue to exist for evaluation must continue for years. No disease as formidable as malaria is easily conquered.

**Suppression.** For the suppression of malaria two compounds, *chloroquine* (Aralen) and *amodiaquine* (Camoquin) have had wide laboratory, experimental and field trials and thus far have proved to be eminently satisfactory. The use of chloroquine was compulsory among the troops in the endemic areas of Korea. Malaria, although acquired, remained at subclinical levels and no problem was recognized until infections appeared in this country among those exposed and who had discontinued the drug. The suppression of malaria is indicated in persons traveling or living in endemic areas of malaria such as soldiers, laborers and others. Thus far neither chloroquine nor amodiaquine has been used on a large scale in native populations. Both of these drugs require only one dose weekly, are readily absorbed and have not been observed to produce any untoward or disagreeable side effects.

The dosage of chloroquine diphosphate (Aralen) is 0.5 gm (two tablets) weekly, taken the same day each week. For heavily endemic areas the dose can be increased by one to two tablets for adults. Amodiaquine (Camoquin) 4 [7-chloro-4-quinolylamino]-4-diethylamino-o-cresol is also equally effective at two or three tablets (0.4 to 0.6 gm) once weekly.

**Pyrimethamine** (Daraprim), a new compound, has had considerable trial and is very useful as a suppressive agent but it is contraindicated for the therapy of the acute illness because of its slow action. Moreover, in experimental infections, strains of parasites resistant to this drug have emerged.

**Therapy for the Acute Attack.** Either chloroquine or amodiaquine is recommended for an acute attack of malaria, either for the first illness or a relapse. The therapeutic action of these drugs is exceedingly prompt without toxic reactions. Neither of these compounds will result in an eradication of infection for vivax malaria but will do so for falciparum infections.

The usual chloroquine regimen consists of an initial dose of 1.0 gm (four tablets) followed by 0.5 gm (two tablets) after six hours. On the second and third day 0.5 gm (two tablets) is given.

Quinine and quinacrine (Atabrine) are

inferior to the more recently discovered compounds and are not recommended.

**Radical Cure.** Vivax malaria has a constant tendency to relapse despite treatment with the maximal tolerated amounts of antimalarial drugs and their administration over an extended period. The only drugs thus far shown to be effective in the complete eradication of a chronic vivax malaria are the 8-aminoquinoline compounds. Pamaquine (Plasmochin) was the first to be recommended but has now been discarded in favor of primaquine, a more effective and less toxic derivative. Primaquine has been tested in many thousand white and nonwhite persons and found to be a safe compound when given in the recommended dosage. When tested for its curative value in experimental and naturally acquired infections, it was demonstrated to be effective. In doses of 15 mg (base) daily for fourteen days, primaquine has reduced the relapse rates in Korean vivax malaria to less than 1 per cent by destroying the tissue stages of the parasite. Since primaquine is relatively ineffective against the asexual blood stages, it should be used in combination with chloroquine. The recommended multiple drug therapy consists of the same chloroquine or amodiaquine regimen as used in acute attacks and the additional concurrent administration of primaquine (15 mg) each day for a total period of fourteen days.

The general treatment consists of simple measures aimed at keeping the patient comfortable, especially during the acute paroxysms. In infections complicated by vomiting or diarrhea, special effort should be made to combat dehydration. It is advisable that convalescent patients receive iron in any of the available forms, since it is extremely beneficial in the restoration of hemoglobin deficiency.

## Trypanosomiasis

African trypanosomiasis Chagas disease and *Trypanosoma rangeli* infections will be discussed in this section The last named now considered nonpathogenic is cited only as it concerns differential diagnosis

### AFRICAN TRYPANOSOMIASIS

(African Sleeping Sickness *Maladie du Sommeil* *Schlafkrankheit*)

**Etiology** Two species of *Trypanosoma* are currently recognized as the etiological agents of African trypanosomiasis *T gambiense* of irregular distribution throughout tropical Africa and *T rhodesiense* reported only from East Africa Both species occur in man as polymorphic but typical trypanosomes 15 to 33  $\mu$  in length Multiplication takes place in the blood by longitudinal division into two or occasionally three or more trypanosomes

So far as is known there are no obligatory intracellular tissue stages of these two trypanosomal infections such as are observed with *T cruzi* Both African species may be maintained either in cultures or frozen at  $-70^{\circ}\text{C}$  for indefinite periods

Another cycle of development takes place in *Glossina* (tsetse) biting flies at present established only in Africa Trypanosomes taken in with the blood subsequently undergo extensive migrations in the fly meanwhile changing morphologically multiplying losing and then regaining infectivity Eventually the trypanosomes invade the salivary glands of the fly and are inoculated at the next feeding This cycle in *Glossina* requires ten to thirty five days or more Both sexes are hematophagous and serve as vectors The infection is not hereditary in the fly

**Epidemiology** African trypanosomiasis is contracted following the bite of an infected *Glossina* occasionally congenitally and rarely through blood transfusions or other accidental inoculations

The distribution of the disease depends upon requirements and preferences of the fly *G palpalis* a riverine species may not penetrate adjacent forested areas for more than 200 yards *G tachinoides* likewise riverine requires less moisture and is more hardy than *palpalis* These are the two most important vectors of *T gambiense* The principal vectors for *T rhodesiense* (*G morsitans pallidipes* and *swynnertoni*) are savanna species and can thrive even when the environment is very dry part of the year The flies are now believed to have

preferences for certain types of vegetation a matter of importance in control For these reasons the disease incidence tends to be spotty it is endemic in one spot and another area close by may be free Occupation is important in so far as contact with *Glossina* is favored The disease occurs essentially in lightly settled areas and urbanization automatically establishes conditions unfavorable for *Glossina* once a minimum population density is exceeded

Animals furnish blood for *Glossina* although they are currently considered not to be significant reservoirs of *T gambiense* but more important for *T rhodesiense* Much of these data require re-evaluation because of recent knowledge of food preferences

**Pathology** In African trypanosomiasis lymph node lesions are customary if not distinctive the reticuloendothelial elements are increased and numerous macrophages occur in the sinuses some containing erythrocytes and leukocytes Later sclerosis producing bands of connective tissue gives the nodes an alveolar appearance

Brain lesions are most marked in prolonged cases The meninges may be thick and adherent opaque or simply edematous the maximal changes occur over the convexity The brain at times edematous less frequently shows small hemorrhages and areas of softening The characteristic microscopic finding is a perivascular infiltrate which occurs at all levels (also in the medulla) in which plasma cells are conspicuous and may predominate Mott's morular cells (Russell bodies) are found in the infiltrate scattered throughout the brain and in the cerebrospinal fluid

A pancarditis with myocardial predominance has been described particularly in *T rhodesiense* cases The lesion combines a predominantly mononuclear cell infiltration with a progressive sclerosis

The cerebrospinal fluid shows a progressive increase in cells initially then in protein globulin tests are positive as are various colloidal reactions Dextrose and chloride values are usually low The plasma globulin increases the albumin is normal or reduced the erythrocyte sedimentation rate increases Cold hemagglutinins are frequently present

**Signs and Symptoms** The initial lesion at the site of an infected *Glossina* bite develops and completely regresses in about two weeks At peak development the area is raised reddened and circular may reach a diameter of 3 cm or more and has a darker center The lesion contains numer

ous trypanosomes by the fourth or fifth day—that is before they are usually seen in the blood

If the initial lesion is not perceived as often happens the disease appears to start with constitutional symptoms these are extremely variable as to intensity and time of onset Fever pain disturbances of the sleep pattern asthenia skin rashes anemia edema particularly about the eyes and enlargement of the lymph nodes all occur frequently The most constant and distinctive sign during the early stage is enlargement of the lymph nodes The node draining the initial lesion is first affected later there is generalization The appearance of enlarged posterior cervical nodes during the stage of generalization is known as Winterbottom's sign

Usually the nodes are only moderately enlarged (15 to 20 mm long) They are freely movable firm and elastic and some what painful spontaneously while enlarging but later are painful only on pressure The nodes do not suppurate unless secondarily infected but eventually become fibrous and harder

Meanwhile clinical manifestations reflect the attack on the central nervous system Tremors deep hyperesthesia with delayed onset (Kerandel's sign) and persistent headache may be accompanied by abnormal cerebrospinal fluid findings even early in the course of the disease Romberg's sign patellar and ankle clonus and various types of paralysis or pareses occur later Functional difficulties in walking and in speech result the mentality is affected reflection becomes difficult and there may be abrupt changes of character as well as psychic disturbances

Spontaneous regression is reported but the disease is usually considered to evolve fatally if untreated Nevertheless the progress of the disease is extremely uneven In certain *T. gambiense* areas some infected persons may not plead illness and may perform hard manual labor for years whereas others are severely affected With *T. rhodesiense* the untreated patient may die in six weeks

**Diagnosis** Diagnostic techniques in current use depend upon the visual recognition of trypanosomes in blood cerebrospinal fluid lymph node aspirate and more rarely in bone marrow Blood is examined fresh then if necessary as a hemolyzed stained thick drop If these examinations fail citrated or heparinized blood can be centrifuged three times first at 1000 rpm for three minutes this is repeated on the

supernate finally the trypanosomes are sedimented by twenty minutes at 1500 rpm The cerebrospinal fluid examination usually requires centrifugation

Lymph node puncture is best performed on a node which is large and soft using a medium caliber needle (e.g. a US No 19) about 2 5 inches long After skin disinfection the node is held firmly from below by the fingers of the left hand The sterile needle (without attachment to a syringe) is then inserted rotated and given a few to and fro movements With proper illumination it is possible to see into the shaft and determine whether the puncture has been productive After withdrawal a syringe is fitted the contents expelled and examined If the procedures described are inconclusive mice or rats guinea pigs rabbits or monkeys may be inoculated

Evaluation of these classic methods of diagnosis has become possible with the advent of cultural methods Conventional methods may fail to detect 15 to 20 per cent of the cases may fail to detect trypanosomes in 30 per cent of infected cerebrospinal fluids and not infrequently may result in negative reports on inoculated animals that have developed a latent type of infection The cultural method is not in general use consequently when clinical suspicions are aroused but not confirmed by the laboratory repetition of the conventional procedures should be insisted upon

**Prognosis** The earlier trypanosomiasis is treated the more favorable the outcome Protein estimations of the cerebrospinal fluid furnish a rough guide to the degree of central nervous system damage when the cerebrospinal fluid contains 30 mg of protein it is essential to choose a chemotherapeutic agent which will cross the blood brain barrier

**Treatment** Because of the toxic potential of certain of the drugs used only proved cases of trypanosomiasis should be treated It is important to follow the cell count and protein content of the cerebrospinal fluid with (1) a pretreatment examination (2) a second examination at the end of therapy and (3) a third examination one year or preferably fifteen months later It may not be possible to restore the cerebrospinal fluid to completely normal values but a cell count above 10 with a protein value of 25 mg does not signify cure Agents of possible value in combating drug toxicity should be at hand and if the patient is not hospitalized he should be interviewed daily for evidence of drug intolerance

The introduction by Friedheim of the

Melarsen compounds is resulting in a change in chemotherapeutic practice although the optimal doses of these drugs are not yet agreed upon. The compounds (Melarsen and Mel B) and trypanosamide penetrate into the central nervous system in effective amounts whereas suramin sodium (Antrypol Bayer 205) and pentamidine do not.

Suramin sodium followed by trypanosamide is widely used; however, effective doses vary in different areas. In one satisfactory schedule, suramin sodium is dissolved in sterile distilled water just before use: 10 gm in 250 ml, and all is injected intravenously. Three such doses are given; the second dose three weeks after the first if this is practicable or if not after five days, and the third dose five days later. Trypanosamide is then administered freshly dissolved in distilled water to make a 20 per cent solution. Two grams the usual adult dose is injected intravenously or if need be intramuscularly and repeated every five to seven days to a total of 20 to 45 gm. The precise total varies according to the previous therapeutic results in the area, the response observed, and the previous treatment received. Poor results can be anticipated in *T. rhodesiense* infections and from trypanosamide-resistant strains in which cases Melarsen compounds are used. The most common toxic complication of trypanosamide therapy is optic atrophy; patients should be questioned before each dose to detect suggestive symptoms. Immediate stoppage of treatment may not arrest the optic neuritis and dimercaprol should be employed.

Mel B, a tervalent arsenical composed of melarsen oxide coupled with dimercaprol, is effective at all stages of the disease, acts against both *T. gambiense* and *T. rhodesiense*, and also against trypanosamide-resistant strains of trypanosomes. It is provided as a 3.6 per cent solution in propylene glycol and injected intravenously. In advanced *T. rhodesiense* cases the following schedule has given satisfaction: 2.5 ml of the 3.6 per cent solution of Mel B daily for three days, then one week rest, followed by 3.0 ml, 4.0 ml, and 5.0 ml on successive days, another week of rest, and three daily injections of 5 ml each to total 34.5 ml or 1242 mg for a 50 kg patient. If urgent treatment is not required, pretreatment with suramin sodium (Antrypol) is advantageous. Mel B has also been satisfactory in the treatment of advanced *T. gambiense* cases.

Melarsen, a quinquevalent arsenical, has been recommended for field use in doses not

exceeding 20 mg per kg of body weight in a series of twelve injections, each given at five-day intervals. It has proved valuable in areas where relapses from the trypanosamide treatment of *T. gambiense* infections were a serious problem.

Prophylaxis and Control. Chemoprophylaxis in African sleeping sickness is one of the great achievements of chemotherapy. Three compounds have been produced which, following a single injection, will protect against trypanosomal infection for at least two months and perhaps more; two of these have been widely used in man. Pentamidine, perhaps the most used today, is administered as an aqueous solution, usually of the isethionate intramuscularly and sometimes intravenously, in a dosage of 30 mg per kg of body weight. Suramin sodium (Antrypol) is given in a one-gram dose as previously described. Neither prophylactic should be administered except after full assurance that the patient is not already infected; otherwise this treatment may mask the infection which will progress and become more of a therapeutic problem.

Area control of the disease has been based on chemoprophylaxis combined with chemotherapy. This is an excellent rapid manner of controlling an outbreak. If the chemoprophylaxis is continued, infection rates in the exposed population may fall to extremely low levels and remain low so long as the chemoprophylaxis is adequately maintained. Antigliosina measures involve the use of insecticides such as dieldrin (used at times in "preferential spraying" only), clearing of the vegetation, and whole-sale killing of game. One interesting procedure involves resettlement into relatively dense population centers; it being considered that once such centers are rendered fly-free, normal human activities will be so unfavorable to the fly that its re-entry will be permanently prevented.

#### CHAGAS DISEASE

Chagas disease, caused by *Trypanosoma (Schizotrypanum) cruzi*, is a progressive, noncontagious, insect-transmitted disease established in rural areas of the Americas. In the United States, although *T. cruzi* is enzootic, the Southwest reports of human disease are rare. On presumptive evidence, the infection is believed to occur in Asia.

**Etiology.** *Trypanosoma cruzi* is a typical trypanosome with the following distinctive characteristics: (1) the undulating membrane is scanty with few or no folds; (2) the kinetoplast is extremely large, i.e., ap-

ous trypanosomes by the fourth or fifth day—that is before they are usually seen in the blood

If the initial lesion is not perceived as often happens the disease appears to start with constitutional symptoms these are extremely variable as to intensity and time of onset. Fever, pain, disturbances of the sleep pattern, asthenia, skin rashes, anemia, edema, particularly about the eyes, and enlargement of the lymph nodes all occur frequently. The most constant and distinctive sign during the early stage is enlargement of the lymph nodes. The node draining the initial lesion is first affected, later there is generalization. The appearance of enlarged posterior cervical nodes during the stage of generalization is known as Winterbottom's sign.

Usually the nodes are only moderately enlarged (15 to 20 mm long). They are freely movable, firm and elastic and some what painful spontaneously while enlarging, but later are painful only on pressure. The nodes do not suppurate unless secondarily infected, but eventually become fibrous and harder.

Meanwhile clinical manifestations reflect the attack on the central nervous system: Tremors, deep hyperesthesia with delayed onset (Herandell's sign) and persistent headache may be accompanied by abnormal cerebrospinal fluid findings, even early in the course of the disease. Romberg's sign, patellar and ankle clonus and various types of paralysis or pareses occur later. Functional difficulties in walking and in speech result; the mentality is affected; reflection becomes difficult, and there may be abrupt changes of character as well as psychic disturbances.

Spontaneous regression is reported but the disease is usually considered to evolve fatally if untreated. Nevertheless the progress of the disease is extremely uneven. In certain *T. gambiense* areas some infected persons may not plead illness and may perform hard manual labor for years whereas others are severely affected. With *T. rhodesiense* the untreated patient may die in six weeks.

**Diagnosis.** Diagnostic techniques in current use depend upon the visual recognition of trypanosomes in blood, cerebrospinal fluid, lymph node aspirate, and more rarely in bone marrow. Blood is examined fresh then if necessary as a hemolyzed stained thick drop. If these examinations fail, citrated or heparinized blood can be centrifuged three times, first at 1000 rpm for three minutes, this is repeated on the

supernatant; finally the trypanosomes are sedimented by twenty minutes at 1500 rpm. The cerebrospinal fluid examination usually requires centrifugation.

**Lymph node puncture** is best performed on a node which is large and soft using a medium caliber needle (e.g. a U.S. No. 19) about 2½ inches long. After skin disinfection the node is held firmly from below by the fingers of the left hand. The sterile needle (without attachment to a syringe) is then inserted, rotated and given a few to and fro movements. With proper illumination it is possible to see into the shaft and determine whether the puncture has been productive. After withdrawal a syringe is fitted, the contents expelled and examined. If the procedures described are inconclusive mice or rats, guinea pigs, rabbits or monkeys may be inoculated.

Evaluation of these classic methods of diagnosis has become possible with the advent of cultural methods. Conventional methods may fail to detect 15 to 20 per cent of the cases, may fail to detect trypanosomes in 30 per cent of infected cerebrospinal fluids, and not infrequently may result in negative reports on inoculated animals that have developed a latent type of infection. The cultural method is not in general use, consequently when clinical suspicions are aroused but not confirmed by the laboratory, repetition of the conventional procedures should be insisted upon.

**Prognosis.** The earlier trypanosomiasis is treated the more favorable the outcome. Protein estimations of the cerebrospinal fluid furnish a rough guide to the degree of central nervous system damage when the cerebrospinal fluid contains 30 mg of protein; it is essential to choose a chemotherapeutic agent which will cross the blood-brain barrier.

**Treatment.** Because of the toxic potential of certain of the drugs used, only proved cases of trypanosomiasis should be treated. It is important to follow the cell count and protein content of the cerebrospinal fluid with (1) a pretreatment examination, (2) a second examination at the end of therapy, and (3) a third examination one year or preferably fifteen months later. It may not be possible to restore the cerebrospinal fluid to completely normal values, but a cell count above 10 with a protein value of 25 mg does not signify cure. Agents of possible value in combating drug toxicity should be at hand and if the patient is not hospitalized he should be interviewed daily for evidence of drug intolerance.

The introduction by Friedheim of the

tions are often not immediately associated with lesions

In the brain *T. cruzi* is situated intracellularly as not invariably directly associated with the widespread inflammatory foci which occur at all levels. *T. cruzi* has also been reported from smooth and striped muscle ovaries adrenal cortex bladder thymus liver spleen lymph nodes blood vessels skin lacrimal glands and conjunctivae

**Diagnosis** The diagnosis of Chagas disease usually is made by examination of the blood more rarely by examination of the cerebrospinal fluid or biopsy material. The blood specimen is preferably taken during fever if negative by direct examination it should be prepared as one or more thick drops if necessary this may be repeated on specimens from the buffy coat after light centrifugation of citrated blood.

Cultures frequently succeed when direct examination fails. 10 to 20 ml of citrated or heparinized blood are inoculated directly onto each of a half-dozen blood agar slants (NN or NNN) incubated at 22 to 25°C in the dark and examined weekly for eight weeks. Animal inoculation is also serviceable. Mice and guinea pigs are the most used and young animals are preferred. Young dogs are reported to be the most susceptible. Xenodiagnosis introduced by Brumpt is one of the most sensitive of all methods but requires a specialized laboratory for it requires the feeding of laboratory reared uninfected vectors on the suspects.

If trypanosomes are detected by any of the foregoing methods care is required to distinguish *T. cruzi* from *T. rangeli* which occurs in several of the endemic areas of Chagas disease. *T. rangeli* about 30  $\mu$  in length is about one third longer than *T. cruzi* contains a small subterminal kinetoplast and shows dividing forms in the blood.

Because the preceding methods may fail the complement fixation method (Guerreiro-Machado reaction) is widely utilized in one form or another. It is reported to give false positive reactions in leishmaniasis, and also in chancroid furthermore the significance of a positive reaction in *T. rangeli* infections remains to be evaluated. False negative reactions are said to be rare during the acute phase but a negative reaction during the chronic period is difficult to evaluate.

**Treatment** There is no satisfactory treatment for Chagas disease the unsolved problem being the eradication of *T. cruzi* in intracellular foci. The following are said to have activity on the forms in the peripheral blood: primaquine, pentaquine 7602 and 9736 (Bayer) and Spirotrypan (Hoechst).

**Prevention** Prophylactic and control measures are centered on vector control. Dwellings should be made as insect proof as possible and then benzene hexachloride (gammexane) or dieldrin both of which have residual effects can be applied with satisfactory effect. Infected domestic animals should be destroyed and dwellings adequately protected from re-entry of the insects particularly from animal shelters. Individual prophylaxis in an endemic area involves the avoidance of infected habitations, fine mesh bed nets are effective and it is probably wise to carry a portable bed or hammock and be prepared to sleep al fresco.

### Leishmaniasis

The diseases described under this title are all caused by infection with parasites of the protozoan genus *Leishmania*. A number of specific names have been given to parasites recovered from patients with differing clinical conditions in various parts of the world and in addition from dogs. Such species however have not so far been satisfactorily distinguished. At present three species are generally recognized corresponding to the three diseases described below: namely kala azar, oriental sore or cutaneous leishmaniasis as seen in Mediterranean and Asiatic areas, and American or mucocutaneous leishmaniasis as seen in South and Central America. It should be noted that in certain circumstances cutaneous and mucocutaneous lesions occur in kala azar and that visceral involvement has been reported in American mucocutaneous leishmaniasis. The separation of these diseases and of the parasites associated with them rests on epidemiological, clinical and immunological grounds.

proximately the size of the nucleus and (3) dividing forms do not occur in the blood

Multiplication of the trypanosome in man is cyclical and takes place intracellularly in the tissues particularly in the heart. Apparently the trypanosome penetrates within the myocardial fiber there *Leishmania leptomona*s and *Crithidia* forms develop and finally the mature trypanosomes which are discharged into the blood.

The insect cycle commences when the blood trypanosomes are taken up by *Triatoma* or related *Reduviidae*. This cycle also is multiplicative and after a complicated series of changes in the trypanosomes and of migrations in the intestine infective forms are finally produced which are discharged in the feces of the insect. The trypanosomes are not inoculated accordingly the rapidity with which the insect defecates after feeding determines in part its importance as a vector.

**Epidemiology.** *Trypanosoma cruzi* occurs naturally in man, other animals and hemipterous insects of the family *Reduviidae*. The latter consisting chiefly of *Triatoma*, *Panstrongylus*, *Rhodnius* and related genera are winged capable of short flights and hematophagous at all stages. Some are forest dwellers, most of epidemiological importance are associated with man in rural dwellings but some have adapted themselves to life in cities. Their habits are much like those of bedbugs; they feed at night or in the dark and seek shelter by day.

The insects also feed on a variety of animals wild and domestic some of which develop chronic infections with *T. cruzi* and thus serve as reservoirs. At least thirty-eight species of animals are naturally infected and a number of others are known to be susceptible. Of domestic animals dogs and cats are important reservoirs of wild animals armadillos are often found to carry *T. cruzi* in the United States armadillos house mice a species of opossum and several species of wood rat have been found to be infected.

**Clinical Description.** The initial lesion of Chagas disease involves the eye in 25 to 75 per cent of cases according to the areas from which the reports are obtained. Characteristically the ocular involvement is unilateral accompanied by marked periorbital edema with reddening of the skin, satellite adenopathy and often with enlargement of the lacrimal gland. Pain is usually lacking or mild although there may be slight conjunctival discharge. Marked inflammation suggests another etiology. These symptoms referred to as the *Chagas Romana sign* persist from one to three months and are accompanied by fever.

In about 20 per cent of the cases the initial lesion is cutaneous often occurring on exposed areas of skin. Starting as a small red violet macule somewhat painful and hot it enlarges without becoming appreciably elevated retaining its dark central portion and in a week reaches a diameter of 4 to 7 cm. the skin and surrounding tissue being indurated for a few centimeters beyond. Regional adenopathy is frequent. After two weeks or so the lesion

crusts over, desquamates and regresses slowly often leaving a pigmented scar. An onset with polyserositis and edema is more unusual in nurslings there are often no external manifestations.

Acute stage symptoms frequently merge with those of the initial lesion. In the acute common type of the disease after an onset as described there are intermittent fever often recurring as short bouts throughout a long period, edema, generalized enlargement of the lymph nodes, short lived exanthemata of various types, nodular subcutaneous elements (chagomas) and occasionally ulcerative lesions. The *meningoencephalitic acute type* which occurs most often in nurslings and the very young has convulsive seizures as the outstanding symptom and is often fatal. Patients who recover frequently suffer from permanent mental or physical defects.

**Cardiopathy** is the conspicuous finding in Chagas disease. It occurs in both the acute and chronic forms and is the most important source of symptoms in the chronic phase. The age group involved is from ten to forty-five years. The symptoms which vary with the localization and intensity of the lesions consist of palpitation, dyspnea, epigastric and precordial pain, more rarely vertigo and syncope and later the evidences of peripheral congestive cardiac failure. Roentgenographic examination often shows some degree of cardiac enlargement with predominance in the transverse diameter and for the right ventricle. Electrocardiographic changes are extremely frequent and at times are the only way of detecting the lesion. Arrhythmias of various types are outstanding and particularly common are disturbances following heart block. The evolution of these cases is extremely variable. In Brazil and Argentina the prognosis as regards both invalidism and early death is reported to be distinctly poor elsewhere very nearly total recovery is considered common if not the rule.

**Pathology.** In the heart where lesions are the most frequent and noteworthy the findings are of three chief types: (1) an inflammation predominantly interstitial at the outset, (2) destruction of muscle fibers and (3) the etiological agent *T. cruzi* which may not be found in any other site. The cellular infiltrate is predominantly mononuclear it involves all three cardiac layers but has a myocardial predominance. The inflammation both diffuse and focal may be extremely intense. Muscle fibers first lose their cross striation and stain strongly with eosin subsequently they rupture retracts and form rounded masses or balls of the necrotic material sometimes occurring within phagocytes. *T. cruzi* occurs within muscle fibers in collections varying in size up to about 85 by 11  $\mu$ ; these collec-

tions are often not immediately associated with lesions

In the brain *T. cruzi* situated intracellularly is not invariably directly associated with the wide spread inflammatory foci which occur at all levels. *T. cruzi* has also been reported from smooth and striped muscle, ovaries, adrenal cortex, bladder, thymus, liver, spleen, lymph nodes, blood vessels, skin, lacrimal glands and conjunctivae.

**Diagnosis** The diagnosis of Chagas disease usually is made by examination of the blood, more rarely by examination of the cerebrospinal fluid or biopsy material. The blood specimen is preferably taken during fever, if negative by direct examination it should be prepared as one or more thick drops; if necessary this may be repeated on specimens from the buffy coat after light centrifugation of citrated blood.

Cultures frequently succeed when direct examination fails. 1.0 to 2.0 ml of citrated or heparinized blood are inoculated directly onto each of a half-dozen blood agar slants (NN or NNN) incubated at 22 to 25°C in the dark and examined weekly for eight weeks. Animal inoculation is also serviceable. Mice and guinea pigs are the most used and young animals are preferred. Young dogs are reported to be the most susceptible. Xenodiagnosis introduced by Brumpt is one of the most sensitive of all methods but requires a specialized laboratory for it requires the feeding of laboratory reared uninfected vectors on the suspects.

If trypanosomes are detected by any of the foregoing methods care is required to distinguish *T. cruzi* from *T. rangeli* which occurs in several of the endemic areas of Chagas disease. *T. rangeli* about 30 µ in length is about one third longer than *T. cruzi* contains a small subterminal kinetoplast and shows dividing forms in the blood.

Because the preceding methods may fail the complement fixation method (Guerreiro-Machado reaction) is widely utilized in one form or another. It is reported to give false positive reactions in leishmaniasis and also in chancroid; furthermore the significance of a positive reaction in *T. rangeli* infections remains to be evaluated. False negative reactions are said to be rare during the acute phase but a negative reaction during the chronic period is difficult to evaluate.

In the acute common type of the disease, after an onset as described, there are intermittent fever, often recurring as short bouts throughout a long period, edema, generalized enlargement of the lymph nodes, short-lived exanthemata of various types, nodular subcutaneous elements (chagomas) and occasionally ulcerative lesions. The meningoencephalitic acute type, which occurs most often in nurslings and the very young, has convulsive seizures as the outstanding symptom and is often fatal; patients who recover frequently suffer from permanent mental or physical defects.

**Cardiopathy** is the conspicuous finding in Chagas disease. It occurs in both the acute and chronic forms and is the most important source of symptoms in the chronic phase. The age group involved is from ten to forty-five years. The symptoms which vary with the localization and intensity of the lesions consist of palpitation, dyspnea, epigastric and precordial pain, more rarely vertigo and syncope and later the evidences of peripheral congestive cardiac failure. Roentgenographic examination often shows some degree of cardiac enlargement with predominance in the transverse diameter and for the right ventricle. Electrocardiographic changes are extremely frequent and at times are the only way of detecting the lesion. Arrhythmias of various types are outstanding and particularly common are disturbances following heart block. The evolution of these cases is extremely variable. In Brazil and Argentina the prognosis as regards both invalidism and early death is reported to be distinctly poor elsewhere very nearly total recovery is considered common if not the rule.

**Pathology.** In the heart where lesions are the most frequent and noteworthy, the findings are of three chief types: (1) an inflammation predominantly interstitial at the outset, (2) destruction of muscle fibers and (3) the etiological agent *T. cruzi* which may not be found in any other site. The cellular infiltrate is predominantly mononuclear, it involves all three cardiac layers but has a myocardial predominance. The inflammation both diffuse and focal may be extremely intense. Muscle fibers first lose their cross-striation and stain strongly with eosin; subsequently they rupture, retract and form rounded masses or balls, the necrotic material sometimes occurring within phagocytes. *T. cruzi* occurs within muscle fibers in collections varying in size up to about 85 by 11  $\mu$ , these collec-

and thymol turbidity tests are strongly positive. The latter must be interpreted in the light of the marked hyperglobulinemia. The urine shows nothing remarkable.

Patients with kala azar have a decided lack of resistance to other infections. It is usually considered that those who have recovered are immune to further infection with kala azar but not to other forms of leishmaniasis.

**Symptoms** In the proper sense of the term the incubation period is not definitely known. Symptoms have appeared from three weeks to nearly three years after exposure but the long silent periods should be attributed in part to latent disease. The onset is often sudden with fever and chills but it may be insidious. The diagnosis is occasionally made by accident in asymptomatic patients. Symptoms may be apparently precipitated by unusual exertion or stress. The temperature chart usually shows remittent or intermittent fever. There may be wide daily swings but sustained elevation occurs in some cases. Double or triple temperature peaks in twenty-four hours are not infrequently seen. Chills, sweats, dizziness and headache are common. Other symptoms include malaise, vague pains in muscles, bones or joints, conjunctivitis, coryza, cough, bleeding from the nose or gums, abdominal distention or the presence of an abdominal mass, occasionally nausea and vomiting. Mental changes are rare except that young children may show clouding or rarely convulsions. In many cases symptoms are strikingly vague or few. On examination patients often appear remarkably well in spite of fever. Pallor accompanies anemia. Purpura is occasionally present. Petechiae are unusual findings. Rose spots do not occur. Jaundice is rare. In late cases the skin may become dark, the hair may fall and there is often much loss of weight. Some patients show painless enlargement of groups of lymph nodes. Subcutaneous nodules are found in a few cases. The pulse rate is increased with fever. Rales may be heard in the lungs. In the great majority of cases the outstanding physical signs are splenomegaly and hepatomegaly. Both organs may enlarge rapidly but the diagnosis has been made when enlargement was not detectable. These organs are not usually tender but occasionally a new infarct produces splenic tenderness. Ascites and edema are rare.

In the Sudan some patients with general manifestations of kala azar have cutaneous and mucocutaneous lesions containing Leishman bodies. In this area and in central Asia a

primary cutaneous lesion has been described in some cases.

**Course and Complications** In the absence of treatment the course is usually prolonged often as much as two or three years. Remissions and relapses are common. Fulminating cases are occasionally seen. The commonest complications are bronchitis and pneumonia. The rare development of agranulocytosis has already been noted. Stomatitis and noma may appear in children with advanced disease. Nephritis is an occasional complication. An interesting sequel to kala azar, postkala azar dermal leishmaniasis, has been seen especially in India. This condition develops a year or more after recovery from the generalized disease. The lesions, which take various forms and are considered to be distinct from those of oriental sore, contain Leishmania but are not accompanied by any evidence of visceral infection. The commonest types are hypopigmented macules, a butterfly erythema on the face and relatively later nodules which resemble those of leprosy. The nodules may persist for years.

**Diagnosis** A sojourn or residence in an endemic area, fever, splenomegaly, granulocytopenia and hyperglobulinemia should suggest the possibility of kala azar. Double daily temperature peaks should bring the disease to mind but they are not pathog-

FIG. 42. Kala azar in a Chinese child. Note protuberant abdomen with enlargement of liver and spleen. (Photograph by E. M. Struthers.)

## KALA AZAR

(Visceral Leishmaniasis)

**Definition** Kala azar is a chronic infection caused by *Leishmania donovani* with its principal seat in the reticuloendothelial system. It may affect all the parts of the body and should be regarded as a general disease. The outstanding characteristics are fever, enlargement of spleen and liver, leukopenia, anemia and hyperglobulinemia.

**Etiological Agent** The discovery of the causative agent was reported in 1903 by Leishman and Donovan independently. *Leishmania donovani* is a parasitic protozoon which is found in two forms during its life cycle. In man and other susceptible vertebrates the parasites have roughly oval shapes, are about  $3\ \mu$  long and have no flagella (Leishman Donovan bodies). With Wright or Giemsa stains Leishman Donovan (LD) bodies have pale blue cytoplasm and bright red nuclei; the presence of a kinetoplast which appears as a purplish dot is important. In appropriate insects and in cultures the organisms have spindle-like shapes, are  $14$  to  $20\ \mu$  long and have prominent flagella (leptomonad forms). Neither form has been found outside animal hosts. Both forms succumb rapidly in water or soil. A number of animals are susceptible to artificial infection with either of these forms, certain hamsters being the most useful. Cultures are readily made starting with either form of the parasite.

**Epidemiology** Kala azar is widespread but the areas in which its existence is well known are discontinuous and the importance of the disease varies greatly in localities relatively near one another. The incidence is especially high in parts of China north of the Yangtze River and of eastern India, particularly in Bihar, Bengal and Assam. The disease is endemic in the region about Tashkent in southern Asiatic Russia and occurs in Mesopotamia, Arabia and Turkey. It is present in areas scattered all around the Mediterranean Sea and in a belt across Africa from Eritrea and Kenya through Abyssinia and French Equatorial Africa to Nigeria. Cases have been reported from Argentina, Paraguay, Bolivia, Brazil, Venezuela and Colombia, but so far the disease does not seem to be very important in South America. Autochthonous cases have not been found in the United States, but many imported cases have been reported, especially in soldiers previously stationed in endemic areas. Kala azar is predominantly a disease of childhood and youth, but cases occur at all ages. There is no evidence of any variation in susceptibility between the sexes or among races. Multiple cases have a tendency to occur in small foci and even in particular houses. Occasionally the disease appears in epidemic form.

Sandflies of the genus *Phlebotomus* have been shown to be important vectors of kala azar in India and China. Since various species of *Phlebotomus* exist wherever the disease occurs, these insects may be vectors in other areas. In China and elsewhere a natural reservoir host for *Leishmania* has been

found in dogs. In addition to that in infected human beings, visceral leishmaniasis has been found in a dog imported into the United States from Greece. In endemic areas in India, however, dogs apparently rarely harbor the infection. It is generally assumed that in India kala azar is transmitted by sandflies directly from patient to patient. This may be one of the methods of infection in all endemic areas. Although parasites are present in the stools, urine and nasopharyngeal secretions of patients, there is no evidence that infection arises from these sources. The disease has been inadvertently transmitted by blood transfusion.

**Morbid Anatomy** The principal reaction of the tissues is marked proliferation of the cells of the reticuloendothelial system. Leishman Donovan bodies may be found in all parts of the body, but they are overwhelmingly localized in the cells of this system. Intracellular parasites grow and multiply while the host cells gradually swell and finally disintegrate. The reticuloendothelial proliferation is often so great that other cells are encroached upon or crowded out. The process is most severe in the spleen, liver and bone marrow. In the spleen and liver, marked congestion develops with enlargement which may be enormous. Capsular thickening causes these organs to become firm.

**Pathological Physiology and Chemistry** The most important abnormalities are found in the blood. About 90 per cent of patients have leukopenia, which is largely due to reduction in the number of granulocytes. Leukopenia usually develops early. After the disease is established, counts of 3000 or less per cu mm are common. In rare instances, agranulocytosis is seen. A normal leukocyte count or a moderate elevation is sometimes associated with the presence of an intercurrent infection. There is usually a relative lymphocytosis; sometimes an absolute increase is seen. The same changes occur in the mononuclears. Occasionally (but usually with difficulty) parasitized macrophages or mononuclears are seen in blood smears. Anemia is also characteristic. It develops more slowly than leukopenia and may be absent or trivial in early cases. As a rule, after the first month, hemoglobin values are 40 to 60 per cent of normal and erythrocyte counts are from 2 to 4 million per cu mm. The icterus index is normal. Thrombocytopenia is regularly present, bleeding times and clotting times are in the upper range of normal or somewhat elevated, and clot retraction may be defective, but these changes are seldom extreme. Serum proteins show an increase in globulin (chiefly in the gamma component) which may be so marked that total globulin amounts to 8 or 9 gm per 100 ml. Serum albumin is usually decreased, especially in longstanding cases. A cold precipitable protein has been found in some sera. Bromsulfalein tests give normal results while cephalin flocculation

about 98 per cent of patients (including patients with relapses who are retreated) with the exception that this high cure rate has not been attained in the Sudan where fulminating and drug resistant cases are apparently numerous

**Treatment** When fever, severe anemia or leukopenia or serious complications are present, patients should be kept in bed. Special care should be given to the mouth. Blood transfusions are indicated for severe anemia, leukopenia or bleeding tendency. An antimicrobial drug may be given for an intercurrent infection at the same time as treatment for kala azar. Patients with noma should receive penicillin. Chemotherapy should be started as soon as the diagnosis of kala azar is established unless agranulocytosis is present. Therapeutic tests and "tinkering" treatment are especially unwise. If it is considered necessary to begin treatment without demonstration of the parasite, a full course of the drug in adequate dosage should be given.

Effective therapy of kala azar began with the use of antimony and potassium tartrate but this drug was superseded long ago by pentavalent antimony compounds. Certain aromatic diamidines have proved useful under special conditions as described below.

The use of ethylstibamine (Neostibosan) has been highly successful except in the Sudan. This drug is recommended for first courses in general. It should be given slowly by vein as a 5 per cent solution in sterile distilled water. The solution is relatively unstable and must be freshly prepared for each injection. It should be used as soon as possible without boiling or heating. The first dose for adults is 0.2 gm and subsequent doses are 0.3 gm. Unless untoward effects appear, doses should be given daily until a total of 3.0 to 5.0 gm has been administered. Nausea and vomiting are the commonest side effects. Dizziness, cough, abdominal and muscular pain, diarrhea, renal disturbances, urticaria and increased bleeding are unusual toxic effects. Increased fever is usually the result of the presence of pyrogens in the distilled water. Anaphylactic shock has been reported in rare instances. If agranulocytosis develops, as it may rarely, treatment should be interrupted until this condition has improved but should be resumed as soon as possible. Otherwise, it should rarely be necessary to interrupt chemotherapy completely though it is not infrequently wise to restrict drug administration to alternate days or to re-

duce the dosage when untoward effects appear. Pentavalent antimony compounds which may be used instead of ethylstibamine include sodium antimony gluconate (Pentostam, formerly designated Solustibosan) and stibamine glucoside (Neostam). These drugs are regarded as both less toxic and less effective than ethylstibamine but they possess the advantage that they can be given intramuscularly.

Patients under treatment should be followed closely with special attention to the leukocyte count. The response to therapy is sometimes dramatic, sometimes slow. Fever is usually absent after the first two weeks but may persist briefly after completion of treatment. The leukocyte count is generally normal in three or four weeks. Improvement in the erythrocyte count is heralded by a marked increase in reticulocytes. It may take many weeks for erythrocytes and hemoglobin to become wholly normal. Serum proteins take three to six months to reach normal values. The spleen and liver often recede rapidly but in long-standing cases the spleen may remain large for months. Cure may follow a single course of therapy even though progress is slow. The treatment outlined rarely fails entirely but 5 to 10 per cent of patients relapse. Most relapses occur within two months but the interval is sometimes four or five months. Patients should be followed for six months before being declared cured. Relapses are usually marked by the return of fever followed by the characteristic picture. The continued presence for a few weeks of *Leishmania* alone does not necessarily indicate that a relapse will occur but clinical suggestions of a relapse should be confirmed by demonstration of the parasite. When the occurrence of a relapse is established, another course of treatment should be given. This may again consist of ethylstibamine in which case larger doses are desirable (up to 0.5 gm a day for twenty days). Such second courses have cured many patients. Or recourse may be had to one of the newer drugs.

The diamidines, stibamidine isethionate and pentamidine isethionate have given better results than pentavalent antimonials in the treatment of kala azar in the Sudan and in some resistant cases elsewhere although they have not been found more satisfactory in general. These drugs have potentially great toxicity which calls for special care in their use. In most areas they are best held in reserve for cases resistant to pentavalent antimonials. Stibamidine

nomonic The formol gel test and the antimony test which depend upon the presence of hyperglobulinemia and hypoalbuminemia are helpful in the Far East These tests however may be negative in the first few weeks of the disease and are positive in certain other diseases though rarely to the degree commonly seen in kala azar Actual measurement of serum globulin and albumin supplies data useful both in diagnosis and in following the course of treatment

The formol gel test is done by adding 1 or 2 drops of formalin to 1 ml of clear serum Complete opacity within twenty four hours constitutes a positive result Partial opacity is a doubtful result and a persistently clear serum is negative even though it gels

The antimony test consists in diluting serum ten times with distilled water and adding to 2 ml of diluted serum the same amount of 4 per cent solution of ethylsubamine (Neostibosan) in distilled water The materials are mixed by rotating the test tube between the palms A positive result is indicated by a heavy flocculent precipitate a doubtful one by mere clouding and a negative one by complete absence of precipitation

The diagnosis should always be confirmed by demonstration of the parasite Although L-D bodies are probably always present in the blood of active cases they are usually so difficult to find that reliance should not be placed on blood smears A small amount of tissue for examination should be obtained from one of the sites in which parasites are normally plentiful which include spleen liver sternal bone marrow lymph nodes and skin lesions The simpler procedures for obtaining the necessary material are aspiration of sternal bone marrow or enlarged lymph nodes and excision of lymph nodes or nodules The spleen has been shown however to be the most reliable source of diagnostic material Spleen puncture is commonly regarded as presenting serious danger although it has been done in thousands of cases in the Far East with only rare accidents The procedure is not free from risk but experience amply justifies its use with proper precautions when bone marrow or lymph node material is negative in a case in which kala azar is a reasonable possibility It is important that the spleen extend well below the costal margin and that the bleeding and clotting times be within normal limits The technique is described in detail by Most

The tissue obtained should be prepared with a Giemsa or Wright stain The parasites probably live mostly within other cells but since macrophages are often ruptured in making smears extracellular Leishman Donovan bodies are common in such preparations They should not be confused with platelets Several preparations should be persistently searched for parasites conforming to the description given previously

When prolonged study of smears is fruitless one can rely on cultures or if a suitable species is available on animal inoculation Both methods are highly successful The material used is generally the same as that for smears the leukocyte layer of 10 ml of centrifuged citrated blood may also be tried Cultures are made on rabbits blood agar medium (Nicolle Novy Mc Neal NNN) and are incubated at 22° C Special care must be taken throughout to maintain aseptic technique In one to four weeks actively motile leptomonal forms may be found on high power search of a sample mixed with a little saline solution on a slide The organisms are sometimes best found in the water of condensation Details should be studied in stained smears The usual laboratory animals are refractory to infection with Leishmania but several species of hamster are highly susceptible Intratesticular inoculation of rabbits has been successfully used for diagnostic purposes Complement fixation agglutination and skin sensitivity tests have been used but their practical value is uncertain

**Differential Diagnosis** In differential diagnosis various forms of leukemia have been the most frequent cause of confusion in the United States Hodgkins disease and infectious mononucleosis have also been diagnosed here instead of kala azar Histoplasmosis which closely resembles kala azar in some instances can be separated only by close attention to the comparative characteristics of the parasites Many other diseases may superficially resemble kala azar notably malaria but also brucellosis typhoid fever bacterial endocarditis disseminated lupus tuberculosis Weil's disease relapsing fever and schistosomiasis In all these instances the separation must be made by close study of the history and clinical picture and by use of applicable laboratory tests

**Prognosis** In the absence of treatment about 75 per cent of patients die often with an intercurrent infection and usually within two or three years Spontaneous recovery has been observed in rare proved cases Good treatment ultimately cures

about 98 per cent of patients (including patients with relapses who are retreated) with the exception that this high cure rate has not been attained in the Sudan where fulminating and drug resistant cases are apparently numerous

**Treatment** When fever severe anemia or leukopenia or serious complications are present patients should be kept in bed. Special care should be given to the mouth. Blood transfusions are indicated for severe anemia leukopenia or bleeding tendency. An antimicrobial drug may be given for an intercurrent infection at the same time as treatment for kala azar. Patients with noma should receive penicillin. Chemotherapy should be started as soon as the diagnosis of kala azar is established unless agranulocytosis is present. Therapeutic tests and "tinkering treatment are especially unwise. If it is considered necessary to begin treatment without demonstration of the parasite a full course of the drug in adequate dosage should be given.

Effective therapy of kala azar began with the use of antimony and potassium tartrate but this drug was superseded long ago by pentavalent antimony compounds. Certain aromatic diamidines have proved useful under special conditions as described below.

The use of ethylstilbammine (Neostibosan) has been highly successful except in the Sudan. This drug is recommended for first courses in general. It should be given slowly by vein as a 5 per cent solution in sterile distilled water. The solution is relatively unstable and must be freshly prepared for each injection. It should be used as soon as possible without boiling or heating. The first dose for adults is 0.2 gm and subsequent doses are 0.3 gm. Unless untoward effects appear doses should be given daily until a total of 3.0 to 5.0 gm has been administered. Nausea and vomiting are the commonest side effects. Dizziness, cough, abdominal and muscular pain, diarrhea, renal disturbances, urticaria and increased bleeding are unusual toxic effects. Increased fever is usually the result of the presence of pyrogens in the distilled water. Anaphylactic shock has been reported in rare instances. If agranulocytosis develops as it may rarely treatment should be interrupted until this condition has improved but should be resumed as soon as possible. Otherwise it should rarely be necessary to interrupt chemotherapy completely though it is not infrequently wise to restrict drug administration to alternate days or to re-

duce the dosage when untoward effects appear. Pentavalent antimony compounds which may be used instead of ethylstilbammine include sodium antimony gluconate (Pentostam formerly designated Solustibosan) and stilbammine glucoside (Neostam). These drugs are regarded as both less toxic and less effective than ethylstilbammine but they possess the advantage that they can be given intramuscularly.

Patients under treatment should be followed closely with special attention to the leukocyte count. The response to therapy is sometimes dramatic sometimes slow. Fever is usually absent after the first two weeks but may persist briefly after completion of treatment. The leukocyte count is generally normal in three or four weeks. Improvement in the erythrocyte count is heralded by a marked increase in reticulocytes. It may take many weeks for erythrocytes and hemoglobin to become wholly normal. Serum proteins take three to six months to reach normal values. The spleen and liver often recede rapidly but in long standing cases the spleen may remain large for months. Cure may follow a single course of therapy even though progress is slow. The treatment outlined rarely fails entirely but 5 to 10 per cent of patients relapse. Most relapses occur within two months but the interval is sometimes four or five months. Patients should be followed for six months before being declared cured. Relapses are usually marked by the return of fever followed by the characteristic picture. The continued presence for a few weeks of *Leishmania* alone does not necessarily indicate that a relapse will occur but clinical suggestions of a relapse should be confirmed by demonstration of the parasite. When the occurrence of a relapse is established another course of treatment should be given. This may again consist of ethylstilbammine in which case larger doses are desirable (up to 0.5 gm a day for twenty days). Such second courses have cured many patients. Or recourse may be had to one of the newer drugs.

The diamidines stilbamidine isethionate and pentamidine isethionate have given better results than pentavalent antimonials in the treatment of kala azar in the Sudan and in some resistant cases elsewhere although they have not been found more satisfactory in general. These drugs have potentially great toxicity which calls for special care in their use. In most areas they are best held in reserve for cases resistant to pentavalent antimonials. Stilbamidine

is both more efficacious and more toxic than pentamidine. It is essential that these drugs be used in freshly prepared solutions. The action of light on solutions produces dangerous hepatotoxic compounds. A number of immediate reactions to intravenous injection including circulatory collapse may occur especially with stilbamidine and particularly with rapid injection. After a course of stilbamidine (sometimes months later) a peculiar neuropathy usually having a trigeminal distribution appears in some cases. Stilbamidine must be given intravenously the daily dose being dissolved in 200 ml of sterile fluid. For adults the first dose is 25 mg. In the absence of untoward effects the dose is increased each day by 10 to 20 mg until the dose of 150 mg is reached. The total amount in a course varies usually falling between 2.0 and 4.0 gm. Pentamidine can be given intravenously in doses of 2.0 to 4.0 mg per kg of body weight dissolved in 200 ml of sterile fluid or it can be given intramuscularly in similar doses dissolved in 5 ml of sterile fluid. The total dose for a course is from 2.0 to 4.0 gm.

In rare cases several courses of treatment with proper doses of antimonial and diamidine drugs are unsuccessful. In a few such instances in which the spleen remained large and firm splenectomy has been quickly followed by apparent cure. This operation should be considered in such cases but it should not be done unless the patient has had more than one course of chemotherapy and it should also be followed by a full course of chemotherapy.

Postkala azar dermal leishmaniasis is relatively refractory but the best available treatment is a full course of ethylstilbamidine as outlined for the visceral stage.

**Prevention** The source of the infection should be attacked by treatment of patients and in areas where dogs are infected by suitable steps against such animals. The sandfly vector should be attacked by removing the conditions in which they abound. Cracks and dark corners in walls and floors, rubbish and vegetation in and around houses should be eliminated. DDT residual spray is effective. Ordinary screens and sleeping nets do not exclude sandflies but sprayed thoroughly with DDT or impregnated with repellent they do constitute a barrier. Sandflies bite mostly after sunset. Clothing is protective except near openings. A repellent such as dimethylphthalate applied to exposed skin keeps sandflies off for four to five hours.

## CUTANEOUS LEISHMANIASIS

(Oriental Sore)

**Definition and Incidence** This name is given to an infection which is characterized by cutaneous granulomas with a strong tendency to ulceration. In cases classified under this heading the disease is limited to the skin there being no evidence of involvement of other parts of the body. It was formerly known by many local names such as Aleppo boil. Its distribution is focal but widespread with centers in western India, southwestern Asiatic Russia, Iran, Iraq, Turkey, Arabia, all countries bordering on the Mediterranean Sea, Abyssinia, the Sudan, French Congo and Nigeria. Similar cases occur throughout Central and South America but it is uncertain that they are distinct from mucocutaneous leishmaniasis. A number of imported cases have been seen in the United States.

**Etiology and Pathology** The disease is caused by protozoa of the genus *Leishmania* which are known as *Leishmania tropica*. Many parasitologists agree that this parasite cannot be reliably distinguished from *Leishmania donovani*; the characteristics of which were previously described. Sandflies of the genus *Phlebotomus* have been shown to transmit the disease from person to person and this is believed to be the common method of transmission. Animal reservoirs however are probably important. They exist in the dog in many areas and in the gerbil (a small rodent) in Asiatic Russia. The evidence indicates that this form of cutaneous leishmaniasis is transmitted by other species of sandflies than those responsible for the spread of kala azar. Direct inoculation from a sore sometimes occurs but is rare. The pathology is that of the local lesion. The basic change is an infiltration of all the layers of the skin mainly by reticuloendothelial cells (macrophages) which behave as they do in kala azar. The circulation is interfered with and necrosis occurs followed by ulceration, granulation and with healing the proliferation of fibrous tissue. The infection is usually followed by immunity at least to the same strain of *Leishmania tropica* but apparently not to kala azar.

**Symptoms** The period from infection to manifest disease extends from a few weeks to two or three years. Systemic symptoms are rare and consist only of transient slight fever and malaise. The lesions are usually multiple, sometimes solitary. They are commonly located on exposed surfaces, espe-

cially the face ears neck backs of the hands and forearms The scalp palms and soles escape In its earliest stages the lesion takes the form of a small red papule which often itches A slight exudate gives rise to fine adherent scales The papule enlarges slowly until in the course of a month or two it is 1 to 3 cm in diameter A thick rupia like scab usually forms Necrosis ordinarily takes place in the center of this lesion resulting in the formation of a roughly circular ulcer with clear cut margins which bleeds easily Pyogenic infection is common at this stage The surrounding area is somewhat swollen and indurated In addition to this typical evolution the lesion may take various other forms The infection is characteristically indolent usually lasting a year or more but occasionally sores follow an abortive course Fairly large lesions heal slowly with the formation of a contracted scar which is often disfiguring

**Diagnosis** In endemic areas the diagnosis is often based on the clinical picture but the lesions may be confused with those of many other diseases including syphilis yaws tuberculosis leprosy and various mycoses The diagnosis should always be confirmed by the demonstration of *Leishmania tropica* which can usually be found with out difficulty in stained smears or NNN cultures of material from early lesions In large lesions material for examination should be obtained by puncturing or scraping the cleaned edges It is useless to study the central exudate Skin sensitivity tests have been used but their value is uncertain

**Treatment** This form of leishmaniasis responds less satisfactorily to chemotherapy than kala azar Cure and healing often require several weeks Numerous agents have been used but there is no general agreement as to the best method of treatment On account of the relatively benign nature of the disease treatment is usually given by local applications or injections Among the agents so used with success are superficial radiation solid carbon dioxide and by local injection berberine sulfate (2 per cent solution) quinacrine hydrochloride (10 per cent) subamine glucoside (Neostam) and other pentavalent antimony preparations (2 per cent) Local injections should consist of about 2 ml given in various points on the periphery of the lesion at weekly intervals Judicious debridement of large ulcers is recommended Secondary infection should be treated by the systemic administration of

an appropriate antimicrobial drug The pentavalent antimony compounds used for kala azar are sometimes given intravenously for oriental sore but the results are not clearly superior to those following local treatment A somewhat less intensive course of one of these drugs than that recommended for kala azar is advisable when the lesions of oriental sore are numerous

Efforts to prevent this form of leishmaniasis should follow the lines laid down for kala azar In addition lesions should be protected so that sandflies and other insects do not have access to them In highly endemic areas advantage is taken of the immunity which usually follows infection to protect selected persons against disfigurement by artificial inoculation of living parasites in inconspicuous areas

#### AMERICAN MUCOCUTANEOUS LEISHMANIASIS

(Espundia and Other Local Names)

**Definition and Incidence** This form of leishmaniasis which is attributed to *Leishmania brasiliensis* resembles the oriental cutaneous type in that it is characterized by skin granulomas but in addition many cases show ulcerative lesions of the nose mouth and pharynx The infection is endemic in most if not all Central and South American countries and in the Yucatan peninsula (Mexico) It is especially common in forested areas It is considered to be distinct from kala azar which also occurs in certain parts of South America

**Etiology and Pathology** The disease is caused by *Leishmania* assigned to the genus *L. brasiliensis* although the organisms cannot be reliably separated from those responsible for the other forms of human leishmaniasis Sandflies are capable of transmitting the infection The parasite has been recovered from dogs but dogs do not seem to be an important source of human disease The basic pathological changes are similar to those in oriental cutaneous leishmaniasis but in many cases the infection spreads regionally through local lymphatic or blood channels producing involvement of the naso oral mucosa and neighboring lymph nodes Visceral involvement resembling that of kala azar has recently been reported

**Symptoms** There are usually three or four skin lesions but often only one and rarely a large number located on exposed parts of the body In form the lesions often resemble those of oriental sore Ulceration

may not appear for months or even years and sometimes does not occur. In the absence of ulcer formation the lesion may acquire a verrucous form. In a few cases nodules are formed along lymphatics and regional lymph nodes are enlarged. The incidence of mucosal lesions is variable in different areas but reaches 20 per cent in Brazil. These lesions usually appear about a year after the skin lesions occasionally only many years later. They begin as swellings which ulcerate and slowly spread so that they may become extensive and cause serious destruction anywhere in the nose, mouth or pharynx. The infection is persistent often lasting for many years if not for life in the absence of treatment. Secondary infection of ulcerated areas is common and may be fatal. Enlargement of liver and spleen with hyperglobulinemia has been described in a few cases.

**Diagnosis** The diagnosis should always be based on the demonstration of the parasite which is recoverable from the more recently invaded tissue of skin and mucosal lesions. In many cases the organism can be found in material from regional lymph nodes and from the nasal mucosa even in the absence of mucosal lesions. Appropriate methods were described for kala azar.

**Treatment** No standard plan is generally recognized but the use of both local and systemic therapy is recommended for most cases. Local treatment of skin lesions should follow the lines suggested for oriental cutaneous leishmaniasis. For systemic treatment the standard intravenous course of a pentavalent antimonial used against kala azar deserves careful trial which it has not yet had. Snapper has described the successful treatment of a patient with mucosal lesions by the use of a stilbamidine derivative. The parenteral therapy most frequently used has consisted either of antimony and potassium tartrate or of stibophen (Fuadin) both given intravenously. Extensive mucosal lesions require much attention. The persistence and pains used to secure and maintain cleanliness are more important than the particular drug applied locally. Sodium perborate or boric acid solution may be used. Systemic treatment with a suitable antimicrobial drug should be given for concurrent infections. Patients should be followed for a year to see that mucosal lesions do not develop or recur. The prevention of this disease follows the recommendations given for kala azar and oriental cutaneous leishmaniasis.

## Toxoplasmosis

**Etiology** *Toxoplasma gondii*, probably a protozoan, is a crescentic organism 4 to 6  $\mu$  long and 2 to 3  $\mu$  wide which causes acute, chronic and asymptomatic infections. Toxoplasma infections have been reported from numerous birds and mammals. Of importance to man are infections of dogs, cats, pigeons, chickens, rats, rabbits, guinea pigs, swine, sheep and cattle. Human toxoplasmosis is widespread in North, South and Central America, Europe, Asia and Africa.

**Life Cycle** *Toxoplasma gondii* lives intracellularly in the reticuloendothelial system in parenchymal cells and extracellularly. Large aggregations of parasites form pseudocysts in various organs. Reproduction is by longitudinal binary fission. Except for transplacental transmission the mode of spread from man to man is unknown. Transmission through respiratory droplets, feces, arthropods and uncooked infected pork have all been suggested with some experimental or epidemiological evidence.

**Morbid Anatomy** In toxoplasma infection of infants the organism is widely disseminated with inflammatory and necrotizing lesions in the heart, lungs, adrenals, central nervous system, eyes and striated muscles. In infants who survive more than the first few days after birth the parasites disappear from most sites and regression of lesions takes place except in the central nervous system and eyes. The brain shows widespread changes consisting of meningoencephalomyelitis, large areas of necrosis, cyst formation and calcification. The spinal cord may be similarly affected. In adults the outstanding gross lesions at autopsy have been limited to the lungs and resemble those of interstitial pneumonia of viral origin.

**Symptoms** There are two types of disease produced in man by toxoplasma: congenital and acquired. Acute congenital infections are characterized by hydrocephalus or microcephaly, convulsions, tremors, twitchings, contractions of the extremities, paralysis, opisthotonos, microphthalmos.

endophthalmos and nystagmoid movements. Chorioretinitis is almost a constant feature of congenital toxoplasmosis. The cerebrospinal fluid is xanthochromic, contains an increased number of erythrocytes and mononuclear cells and has a high protein content. Jaundice, hepatosplenomegaly, thrombocytopenia and purpura may be present. Roentgenographic examination of the skull reveals small areas of calcium density. Infants who survive the infection exhibit chronic hydrocephalus or microcephaly, convulsions, paraplegia, speech defects and defective vision.

The acquired infection assumes several forms. In the acute disease there may be a maculopapular rash, pneumonitis, cough, fever, headache, arthralgia, myalgia, lymphadenopathy, conjunctivitis and myocardial involvement. Subacute infections exhibit lymphadenopathy with or without fever. There is a subclinical form in which the patient has no fever nor does he complain of lymph node enlargement, but lymphadenopathy is discovered on physical examination. Lymphocytosis of 50 to 70 per cent is common in acquired infections and atypical mononuclear cells consistent with infectious mononucleosis may be present. Chorioretinitis and uveitis have been reported a number of times in acquired adult toxoplasmosis.

**Diagnosis.** The signs and symptoms of congenital toxoplasmosis are highly suggestive but the acquired infections are often mild and unsuspected. The cerebrospinal fluid is xanthochromic, contains an increased number of cells and has a high protein content. Serological tests have been widely used as aids in diagnosis and are of greatest significance in congenital infections. The dye test of Sabin and Feldman usually becomes positive early in the infection and persists for several years. This test is based on the fact that toxoplasmas incubated in normal serum stain with methylene blue while those incubated in antibody-containing serum lose their affinity for the stain. A toxoplasma complement fixation test is available. In general the dye test becomes positive before the complement fixation test rises to a higher titer and remains positive after the complement fixation test has reverted to negative. An intradermal test is available but as it is less specific than the other tests it is of limited clinical value.

**Prognosis.** Acute congenital toxoplasmosis is usually fatal and children surviving it are often incapacitated. Acquired infections vary greatly depending upon the

organs involved. Many are asymptomatic. Mothers who give birth to toxoplasma-infected children give birth subsequently to normal noninfected children.

**Treatment.** As the course of toxoplasmosis varies considerably and the lesions tend to spontaneous arrest, it is difficult to evaluate the effects of chemotherapy. Sulfonamides in conjunction with pyrimethamine (Daraprim) appear to be promising. Successful results have been reported from the use of triple sulfonamide (equal parts of sulfadiazine, sulfamerazine and sulfamethazine) in an initial dose of 3.0 gm followed by 1.0 gm every four hours in conjunction with pyrimethamine 50 mg initially, 25 mg six hours later, then 25 mg daily. This multiple-drug therapy was continued for fourteen days. Adrenal corticosteroids are reported to be of value in acute exacerbations of chronic lesions.

## Ciliate Infections

### BALANTIDIASIS

**Etiology.** Balantidiasis is an infection of the large intestine with *Balantidium coli*, characterized by disturbances varying from a mild colitis to acute dysentery. *B. coli* is a large (100 by 60  $\mu$ ) egg-shaped ciliate containing a large kidney-shaped macronucleus and a small micronucleus. The trophozoites are the pathogenic stage and under unfavorable conditions they may produce a protective wall and become cysts.

**Morbid Anatomy.** The trophozoites invade the mucosa, submucosa and muscularis chiefly of the cecum and upper portion of the large intestine and less commonly the small intestine in the area of the ileocecal valve. Cytolytic enzymes and mechanical penetration are probably involved in the parasite's tissue invasion. It feeds on erythrocytes, leukocytes, tissue fragments and intestinal debris.

The early intestinal lesions consist of minute hemorrhages round cell infiltration and eosinophilia. Multiplying trophozoites form small submucosal abscesses that break down into ulcers with undermined edges. Intestinal perforation may occur. It is believed by some that bacteria are necessary for the invasion of tissues by *Balantidium*. The chronic lesions are frequently complicated by secondary bacterial invaders. Although trophozoites have been found in mucosal blood vessels and lymphatics invasion of the liver or other organs has not been reported.

**Epidemiology** Human infections with *B. coli* have been reported from most areas of the world. Infection of hogs with *Balantidium* is very prevalent and this form is considered to be the source of human infection. The monkey, chimpanzee, rat and guinea pig harbor species of *Balantidium* indistinguishable from the human form. Shookhoff reported twenty infections among Puerto Ricans, the majority of whom were children. Eighteen of twenty of his patients reported close contact with hogs. Association with hogs by only 25 to 50 per cent of the patients of other studies suggests other sources of infection. Institutional infections indicate person-to-person transfer. Transmission is through the ingestion of cysts in water and food contaminated by infected feces. Handling hogs in slaughter houses and on farms may lead to infection.

**Symptoms** In Shookhoff's group of twenty patients only ten had symptoms referable to the infection; the remainder appeared to be asymptomatic carriers. Of those with symptoms eight had diarrhea, four had abdominal pain and two had anorexia. One child of three years of age had diarrhea for two years. Anemia and slight leukocytosis with eosinophilia were present in several of this group. In severe infections there is dysentery with six to fifteen bowel movements per day, abdominal pain, nausea, vomiting, headache, weakness and fever. Strong collected 111 severe cases and found a mortality rate of 29 per cent. The mortality rate in 57 mild infections was 7 per cent. Fatal infections show extensive multiple diffuse ulceration, gangrene and perforation.

**Diagnosis** The clinical picture of balantidiasis may resemble that of intestinal amebiasis. The diagnosis is made by finding the trophozoites or cysts in the patient's stool. The large size of the trophozoite and its constant movement "ploughing through the liquid fecal film" make it easy to find.

**Treatment** Iodoquin, carbarsone and the tetracycline drugs are the agents of greatest therapeutic value in balantidiasis. Their relative efficacy has not been determined in large enough groups of patients to be significant. Iodoquin because of its efficacy, safety and cost is preferred. A dose of 0.65 gm three times a day for twenty-one days is given to all patients ten years of age or older. Children one to four years of age are given 0.21 gm three times a day and those five to nine years of age 0.42 gm three times a day for twenty-one days. Secondary bacterial infection should be treated with a tetracycline or sulfonamide. Supportive therapy consisting of fluids, vitamins and adequate diet and iron is indicated in severe and chronic infection.

**Prevention** The prevention of balantidiasis consists in care not to contaminate food or drink with human or porcine feces. The usual precautions against such transmission should be taken: handwashing, proper disposal of excreta, treatment of carriers and health education.

## METAZOAN INFECTIONS

Metazoa are invertebrate animals made up of many cells which in aggregates are usually specialized into tissues and organs performing particular but coordinated functions of the entire organism. In this respect metazoa differ from protozoa the one-celled organisms in which all the functions are performed by specialized parts of the protoplasm within a single cell unit. The parasitic metazoa are found primarily

within the following invertebrate groups

- A Platyhelminthes (flatworms)
  - 1 Trematoda (flukes)

## The Platyhelminthes (Flatworms)

## Trematode or Fluke Infections

## (Trematodiasis)

Trematodiasis is an infection with the species Trematoda or so called flukes. Most flukes infecting man are flat and often leaf like with the mouth at the anterior end surrounded by a muscular sucker and a second ventral sucker for attachment to the host. Except for the schistosomes the flukes infecting man are hermaphroditic. The flukes have a complicated life cycle in addition to man who harbors the adult. A snail intermediate host is always involved. Infection of man takes place by direct penetration of the cercariae (schistosomiasis) or by the ingestion of infected fish, crustaceans or fresh water plants which harbor the metacercariae.

## INTESTINAL TREMATODES

## FASCIOLOPSIS BUSKI

**Etiology.** *Fasciolopsis buski* is a large intestinal trematode which man shares with the hog. It is an important parasite of man in China, the Bengal areas of India and East Pakistan, Thailand, Malaya and neighboring areas.

**Life Cycle.** The adult worms which are hermaphroditic average 3 cm in length and 1.2 cm in breadth. They daily pass thousands of large operculate eggs which are passed in the feces and mature only in water. After several weeks of development a ciliated free swimming miracidium hatches from the egg and actively penetrates its appropriate snail host. A multiplicative cycle takes place in the snail and cercariae are shed which encyst on certain water plants of the genera *Trapa* and *Eelocharis* which when eaten serve as the source of human infection. Large numbers of encysted cercariae metacercariae may be present on the outer layers of water nuts. When eaten raw the nuts are peeled with the teeth freeing the metacercariae which are swallowed and mature into adult worms in three months.

**Symptoms.** *Fasciolopsis* attaches by means of its ventral sucker to the mucosa of the upper small intestines where it feeds on the intestinal contents. Localized foci

of inflammation, ulcerations and abscesses occur at the site of attachment. Erosion of capillaries may result in bleeding. Epigastric pain of varying severity occurs especially in the morning. Food frequently allays the pain but may lead to additional infection in the field through the eating of raw water nuts. Severe diarrhea accompanied by nausea and vomiting may alter state with constipation.

Several thousand worms may be harbored by heavily infected patients. Severe and fatal infections are accompanied by a marked edema, ascites and anasarca. The edema may be due to the absorption of toxic metabolites of the parasite. Anemia is present in some patients. There is a leukocytosis in approximately one half of the patients; however, leukopenia and lymphocytosis may be present. Eosinophilia is common and may reach 34 per cent.

**Diagnosis.** The symptoms of this form of fluke infection (fasciolopsiasis) are sufficiently characteristic when encountered in endemic areas to suggest a stool examination. As a relatively large number of eggs are passed by each worm, even light infection should be detected. The eggs may be confused with those of *Fasciola hepatica*.

**Prognosis.** In severe infections with extensive anasarca the prognosis is grave, especially if anthelmintics are not administered.

**Treatment.** Hexylresorcinol ("Crystoids Anthelmintic") is effective in the treatment of fasciolopsiasis. The adult dose is 1.0 gm and children are given 0.1 gm per year of age up to ten years. A light or liquid meal should be taken the evening before treatment. The drug is administered the following morning on an empty stomach and no food should be taken for four hours. A single treatment cures 54 per cent of the infections and greatly reduces the worm burden of the remainder. Tetra-chlorethylene is also recommended for this infection. Patients recover quickly following therapy.

**Prevention** The prevention of infection with the fluke *Fasciolopsis buski* consists of thorough cooking of vegetables which have been exposed to the infection. Infected persons should be treated and in areas where the infection rate is high mass treatment should be undertaken. Destruction of the snails by the use of copper sulfate is practicable in small plots where the water nuts are grown. Prolonged storage of night soil with slaked lime will destroy the ova of *Fasciolopsis*.

#### OTHER INTSTINAL TREMATODES

Trematodes of various mammals and birds infect people who eat raw or inadequately cooked fish which harbor the metacercariae *Heterophyes heterophyes* or *Metagonimus yokogawai*. The adult worms are 1.0 to 2.5 mm in length and live in the mucosa of the small intestine. Large numbers of these minute parasites cause inflammation of the intestine, diarrhea and abdominal discomfort. Occasionally heterophyid eggs gain access to the mesenteric lymphatics and the blood stream and are carried to the myocardium, brain, spinal cord and kidneys where they cause considerable damage. The eggs of these trematodes which are found in the stool are small, operculate and may be confused with those of *Clonorchis*.

Treatment with tetrachlorethylene (as for hookworm) or hexylresorcinol (as for ascariasis) is recommended, although the habitat of the worms makes them difficult to dislodge. Prevention consists in eating only thoroughly cooked fish.

A number of Echinostomatidae characterized by spines about the anterior sucker have been reported as producing disease in man, although they are normally parasites of birds and mammals other than man. Infection is acquired by eating a variety of small animals raw such as snails, fresh water fish and molluscs. The adult worms live in the small intestine of man and those of the genera *Echinostoma*, *Echinochasmus* and *Paryphostomum* are reported to cause diarrhea and abdominal pain. Therapy with tetrachlorethylene removes large numbers of the worms.

#### HEPATIC TREMATODES

##### CLONORCHIS SINENSIS

(Liver Fluke)

*Clonorchis* is widespread in the Far East including China, Indo-China, Korea and Japan. It is common in dogs and cats in these areas but human infection is limited to areas where fish is eaten raw, pickled or smoked.

**Life Cycle** The adult worms are 10 to 25 mm in length and 3 to 5 mm wide. They live in the bile ducts of the liver and feed upon its secretions. They live as long as twenty-five years. Eggs passed in the bile duct find their way out of the host in the feces. Susceptible snails ingest the ova and after larval development and multiplication free swimming cercariae emerge which encyst on fresh water cyprinoid fishes. Man and mammal become infected by eating raw or partially cooked fish. The metacercariae are digested free of the fish flesh and are liberated in the duodenum. They migrate by way of the ampulla of Vater to the bile ducts of the liver becoming adults in one month.

**Pathology and Symptomatology** The distal bile ducts inhabited by *Clonorchis* are irritated by the parasite and its toxic secretions. The biliary epithelium undergoes an extensive adenomatous proliferation accompanied by a thickening of the duct walls. The dilated portions of the bile ducts are filled with worms and a brownish fluid containing eggs and leukocytes. Bacterial infection may occur and lead to ulceration. Periportal and central fibrosis and fatty changes in the parenchymal cells are frequently encountered at autopsy. As many as 21,000 worms have been found in a heavily infected liver. They also invade the pancreas.

Since the worms are acquired over a long period and since they live twenty to twenty-five years the disease usually has an insidious onset and is chronic. Indigestion characterized by epigastric pain, eructation of gas and nausea are early symptoms. During the early stages of the infection a leukocytosis and marked eosinophilia are often present but they recede as the infection becomes chronic. The liver is enlarged and tender and may be accompanied by a slight icterus. In heavy infections diarrhea, persistent liver enlargement, edema, ascites and cachexia develop. Systemic disease toxicity with tachycardia, palpitation, vertigo, tremor and mental depression have been reported.

**Diagnosis** Patients from endemic areas with a history of eating raw fish with or without symptoms should have a stool examination. The small operculate egg

resembles those of several other hepatic and intestinal flukes. Severe advanced infections must be differentiated from other forms of hepatic cirrhosis malignancy amebic hepatitis and echinococcus cyst.

**Treatment** The therapy of clonorchiasis is not very satisfactory. Gentian violet given orally relieves symptoms in acute clonorchiasis and may cure early light infections. It reduces the number of worms in chronic infections. The adult dose of gentian violet is 65 mg three times a day with meals for thirty days. Repeated courses of therapy are frequently required. Recently acquired light infections may respond to potassium antimony tartrate. Chloroquine 0.5 gm three times a day for two to three weeks relieves symptoms, reduces the numbers of eggs found in the stool in most infections and in approximately one third of the patients results in a cure.

**Prevention** The prevention of infection with this liver fluke consists of thorough cooking of all fresh water fish from endemic areas when preparing them for eating.

#### FASCIOLA HEPATICA (Sheep Liver Fluke)

**Etiology** *Fasciola hepatica* an accidental parasite of man is primarily a parasite of sheep and other herbivorous animals. The sheep liver fluke causing the disease liver rot has a worldwide distribution and human infections though not numerous are similarly widespread. About one third of the reported human infections are from Cuba. Although sheep in the United States are infected and human infections could arise there, all persons infected thus far have also visited other endemic areas. *F. gigantica* of cattle is an infrequent parasite of man.

**Life Cycle** The adult worms 30 mm in length and 13 mm wide live in the bile ducts, liver parenchyma and gallbladder. Their large operculate eggs pass with the bile into the intestine and are evacuated in the feces. The miracidium which hatches from the egg invades a lymnaeid snail where development and multiplication take place. The cercariae which emerge from the snail crawl up on moist vegetation and encyst. The encysted metacercariae are ingested with grass. Man is prob-

ably infected through eating infected watercress or drinking water that contains detached cysts. When they reach the upper small intestine the metacercariae are liberated and burrow through the intestinal wall by way of the peritoneal cavity they enter the liver where they mature. The migrating larvae sometimes go astray and are trapped in various tissues giving rise to ectopic infections.

**Pathology and Symptomatology** In animals the migration of the immature worm through Glisson's capsule and the liver parenchyma may cause considerable damage. The mechanical and toxic action of the parasites leads to hyperplasia of the biliary epithelium with adenomatous cystic dilatation. There is a marked increase in connective tissue of the ducts with portal cirrhosis and pressure necrosis of the parenchyma.

The migration of the young worms through the hepatic tissues gives rise to an enlarged painful liver and fever. The adult worms cause hepatic pain and tenderness, abdominal rigidity, fever and diarrhea. Leukocytosis and marked eosinophilia are present. Acute cholecystitis, obstruction of the common bile duct and jaundice have been reported. In severe infections the patient may exhibit anemia, weight loss and a profound toxicity due to the absorption of toxic products of the worms. The presence of the worm in ectopic locations such as the intestinal wall, abdominal wall, muscles of the neck, brain or eye gives rise to localized symptoms. The ingestion of infected raw sheep and goat liver may lead to halzoun (i.e. suffocation) due to lodgement of the adult worm in the pharynx or larynx of man.

**Diagnosis** The history of hepatic pain, eosinophilia and eating watercress is suggestive of hepatic infection with a fluke and should lead to an examination of the stool for *Fasciola* eggs.

**Prognosis** The prognosis of *Fasciola* disease is good in light infections and poor in heavy infections with severe liver involvement.

**Treatment** Emetine hydrochloride 0.04 gm daily for a total dose of 5 mg per kg of body weight is effective. Carbon tetrachloride is effective but dangerous in the presence of liver damage. Ectopic flukes should be removed surgically.

## OTHER HEPATIC TREMATODES

*Opisthorchis felineus* O. *uterrini* and *Dicrocoelium dendriticum* are liver flukes of man which may produce a clinical picture similar to that of *Clonorchis* O. *felineus* is found in man in East Prussia Poland the USSR and the Far East O. *uterrini* is prevalent in Thailand Both species are common in cats and dogs in endemic areas Man acquires the infection by eating raw fish harboring the metacercaria stage O. *dendriticum* has a cosmopolitan distribution in sheep where it lives in the liver Man becomes infected accidentally by ingesting the ant intermediate host Ingestion of sheep liver harboring this parasite results in the eggs being present in man's stool temporarily an example of spurious parasitism Treatment of these infections is similar to that of clonorchiasis

## PARAGONIMIASIS

(Lung Fluke)

**Etiology** The adult lung fluke *Paragonimus westermani* is thick reddish brown 8 to 12 mm in length and 4 to 6 mm in width and typically lives encapsulated in the lungs The infection in man is wide spread in the Orient especially in Japan Taiwan Korea China the Philippines and Indonesia A few infections have been reported from Africa and South America Only one human infection has been reported from the United States although the adult parasite is present among mammals and the larval form in crayfish

**Life Cycle** The normal site of the adult worm is in the lungs and the eggs are found in the sputum as sputum is swallowed the eggs may appear in the feces The eggs develop in fresh water The liberated miracidium enters a suitable species of snail in which development and multiplication takes place Cercariae emerge from the snail and enter the soft tissues of fresh water crabs and cray fish where they encyst Man dogs cats and many other mammals acquire infections from eating uncooked crabs or crayfish harboring the cysts with metacercariae Infection may be acquired from drinking water which contains detached cysts The metacercariae excyst in the duodenum migrate through the intestinal wall traverse the peritoneal cavity burrow through the diaphragm and enter the lungs where they grow to maturity in eight to nine weeks The eggs find their way into the sputum through ruptured bronchi

**Morbid Anatomy** An eosinophilic neutrophilic infiltration surrounds the growing worm in the lung and gradually a thick fibrous capsule is formed The cysts are 6 to 10 mm in diameter and are surrounded by congested edematous tissue The cyst contains one or more worms in a brownish necrotic gelatinous exudate containing typical operculate eggs The cysts may suppurate ulcerate and resemble tuberculous lesions Aberrant worms wander into various parts of the body and may be found in the abdominal cavity and abdominal wall

liver spleen mesenteric lymph nodes omentum intestinal wall prostate pleural cavity pericardium brain orbital cavity muscle skin and testes

**Symptomatology** The pulmonary disease produced by this lung fluke progresses slowly and resembles tuberculosis in many respects The patients have a cough most pronounced on rising in the morning sputum which is blood stained rusty or purulent occasional attacks of hemoptysis and chest pains Pleurisy is often present Dyspnea fever and anorexia are present in heavy infections There may be slight anemia leukocytosis and eosinophilia The erythrocyte sedimentation rate is slightly increased The physical signs may suggest tuberculosis pneumonia or bronchiectasis A high eosinophilia is often found in the pleural fluid Abdominal infection is characterized by abdominal pain of varying intensity and sites depending upon the organ involved Tenderness and rigidity of the abdomen may be present and with ulceration of the intestine blood and ova may be found in the stool

Cerebral infection produces jacksonian epilepsy with varying degrees of hemiplegia monoplegia visual disturbances and paresis An increased cell count in the cerebrospinal fluid with as high as 60 per cent eosinophils has been reported

**Diagnosis** In endemic areas the clinical symptoms of pulmonary paragonimiasis are suggestive but it must be remembered that in these areas tuberculosis is also very common and that the patient may have both infections Opinions differ as to the value of chest roentgenography in differential diagnosis Nodules up to 4.0 cm in diameter are present The diagnosis is definitely established by finding the eggs in the sputum Eggs in the feces may originate in swallowed sputum or in intestinal lesions Worms lodged in various organs such as the brain cannot be diagnosed by sputum or stool examination A concomitant pulmonary infection may be present A diagnosis of extrapulmonary infection may be made by the complement fixation test Subcutaneous creeping tumors are strongly suggestive of the disease in patients from endemic areas

**Prognosis** As the majority of worms live approximately six years in the absence of reinfection the disease gradually subsides on the death of the worms The prognosis is good in light or moderate infections In heavy infections those with superimposed pyogenic or tuberculous infections or cerebral involvement the prognosis is unfavorable

**Treatment** No effective specific therapy is available at present. Emetine hydrochloride 0.065 gm intramuscularly daily for twelve days temporarily reduces the egg production of the worms. Sulfonamide administered concurrently appears to be of value. Tartar emetic as given for schistosomiasis temporarily relieves pulmonary symptoms.

Recently Chung and Hou reported clinical and parasitological cures with chloroquine which was administered over a period of 93 to 231 days. The total dosage employed varied from 26 g to 85.7 gm.

Infections of the brain can be cured only by surgery.

**Prevention** The prevention of pulmonary paragonimiasis consists in eating only thoroughly cooked crayfish and crabs. Salting, pickling or soaking in rice wine is not sufficient to kill the metacercariae. Infected sputum and feces must be disinfected or kept from water.

## Schistosomiasis

### (Bilharziasis)

**Etiology** Schistosomiasis is a chronic disease caused by the eggs and the adult schistosomes or blood flukes. *Schistosoma mansoni* and *S. japonicum* live in the small venules of the intestine and *S. haematobium* in the vesical and pelvic plexuses. The migration of the eggs through the intestine and urinary bladder and their accumulation in the liver, lungs and central nervous system produce the characteristic syndrome.

**Life Cycle** The delicate adult worms which are 0.6 to 2.5 cm in length reside in pairs, the female lying in the gynecophoric canal of the male. Depending upon the species of worm, from 300 to 3500 eggs are passed daily into the venules. A larval form, miracidium, develops within the egg. Its lytic enzymes and the contraction of the venule rupture the wall of the venule, liberating the egg into the perivascular tissues of the intestine or

urinary bladder. The eggs effect a passage into the lumen of these organs and are evacuated in the feces or the urine. On contact with fresh water, the miracidia hatch from the eggs and swim about until they find an appropriate snail which they penetrate. After two generations of development and multiplication within the snail, the forked-tailed cercarial progeny emerge. During bathing, swimming, working or washing clothes, the skin of man comes in contact with free-swimming cercariae which become attached and burrow down to the peripheral capillary bed as the surface film of water drains off. If ingested with water, the cercariae penetrate the mucous membrane of the mouth and throat. The cercariae are transported through the afferent blood to the right heart and lungs. They squeeze through the pulmonary capillaries and are carried into the systemic circulation. Usually only those which get into the mesenteric arteries and pass through to the portal vessels survive. Within the intrahepatic portion of the portal system, the successful blood fluke larvae feed and rapidly grow. Approximately 20 days after skin exposure, the adolescent worms migrate against the portal blood flow into the mesenteric vesical and pelvic venules.

**Geographical Distribution** *S. mansoni* has an extensive distribution in Egypt, Africa, Madagascar, Yemen, the West Indies and the northern part of South America. *S. japonicum* is found in Central and South China, Japan, the Philippines and Celebes. It is found in domestic and wild mammals in Taiwan, but the strain does not develop to maturity in man. *S. haematobium* is very prevalent in Egypt and throughout Africa. It is present in areas of the Near East, Middle East, Madagascar, Portugal and a small area near Bombay, India. It is estimated that 114,000,000 persons are infected with schistosomes. Next to malaria, it is man's most serious parasitic infection.

## INTESTINAL SCHISTOSOMIASIS

**Symptoms** Intestinal schistosomiasis is caused either by *S. mansoni*, which lives primarily in the venules of the large intestine and to a lesser extent in those of the ileum, or by *S. japonicum*, which inhabits the venules of the small intestine and also the large intestine. The interval between infection and the onset of the acute generalized symptoms is approximately forty days in *S. mansoni* infections and twenty-eight to thirty-five days in *S. japonicum* infections. Eggs first appear in the stool at about the same time. Symptoms may be absent, very mild or may not appear for years in light infections in which there are relatively few eggs produced to injure the host. The adults live up to twenty-five years.

The infection may be divided clinically into three stages: (1) incubational, the period of migration and maturation of the growing worms; (2) acute, the period of egg laying and the escape of eggs into the lumen of the intestine and bladder; (3) chronic, the period of tissue fibrosis when eggs are trapped in the tissues.

The incubation period is initiated by the

penetration of the skin by cercariae which may produce a transient pruritus and rash. During the invasion of the liver and other organs by the immature worms petechial hemorrhages and foci of eosinophilic and leukocytic infiltration are produced. Toxic and allergic reactions may cause urticaria, subcutaneous edema, asthmatic attacks, leukocytosis and marked eosinophilia. Toward the end of the incubation period the liver becomes enlarged and tender and there are abdominal discomfort, fever, sweating, chilliness and sometimes diarrhea.

With the initiation of egg laying the acute stage begins. In the normal cycle the eggs work their way through the intestinal wall and escape in the feces when numerous they are accompanied by blood and necrotic tissue cells. Many eggs are swept back into the blood stream.

Autopsy of 110 persons infected with *S. mansoni* revealed eggs in the following organs: liver 20 per cent, gallbladder 4 per cent, lungs 24 per cent, pancreas 5 per cent, stomach 11 per cent, small intestine 16 per cent, cecum 23 per cent, appendix 8 per cent, ascending colon 29 per cent, transverse colon 36 per cent, descending colon 38 per cent, rectum 44 per cent, suprarenal gland 2 per cent, mesenteric lymph nodes 2 per cent, spleen 2 per cent, urinary bladder 14 per cent, vagina 19 per cent, cervix 6 per cent, uterus 21 per cent, kidney 2 per cent, ureters 1 per cent, prostate 7 per cent, and testes 1 per cent.
